In versions of the architecture that precede Version 2.07, `mspr` specifying the DSCR caused all active and nascent data streams to cease to exist. In those versions of the architecture, the DSCR was used as an overall control mechanism to specify a single global profile for all streams. Beginning with Version 2.07, the DSCR is intended to control and accelerate the creation of new streams without disturbing existing streams.

**Programming Note**

The URG, LSD, SNSE and SSE fields do not affect the initiation of streams specified using the `dcbt` and `dcbtst` instructions.

Note that even when SNSE is not set, hardware may detect Stride-N streams in intervals when they access elements that map to sequential cache blocks.

**Programming Note**

In order for the DSCR to apply the transient attribute to streams, at least two of the four enable bits must be set: one to choose a type of access (load or store), and one to choose a kind of prefetching (software-defined or hardware-detected).
4.3 Cache Management Instructions

The *Cache Management* instructions obey the sequential execution model except as described in Section 4.3.1.

In the instruction descriptions the statements “this instruction is treated as a *Load*” and “this instruction is treated as a *Store*” mean that the instruction is treated as a *Load* (*Store*) from (to) the addressed byte with respect to address translation, the definition of program order on page 735, storage protection, reference and change recording (*S*), and the storage access ordering described in Section 1.7.1 and is treated as a *Read* (*Write*) from (to) the addressed byte with respect to debug events unless otherwise specified. (See Book III-E.)

**Programming Note**

Accesses that are caused by or associated with *Cache Management* instructions that are “treated as a *Load*” or “treated as a *Store*” are not subject to the special ordering rules described for SAO storage. These accesses are always performed in accordance with the weakly consistent storage model.

Some *Cache Management* instructions contain a CT field that is used to specify a cache level within a cache hierarchy or a portion of a cache structure to which the instruction is to be applied. The correspondence between the CT value specified and the cache level is shown below.

<table>
<thead>
<tr>
<th>CT Field Value</th>
<th>Cache Level</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Primary Cache</td>
</tr>
<tr>
<td>2</td>
<td>Secondary Cache</td>
</tr>
</tbody>
</table>

CT values not shown above may be used to specify implementation-dependent cache levels or implementation-dependent portions of a cache structure.
### 4.3.1 Instruction Cache Instructions

#### Instruction Cache Block Invalidate X-form

**icbi RA, RB**

Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the instruction cache of any processors, the block is invalidated in those instruction caches.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the instruction cache of this processor, the block is invalidated in that instruction cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a **Load** (see Section 4.3), except that reference and change recording need not be done.

**Special Registers Altered:**

None

---

#### Instruction Cache Block Touch X-form

**icbt CT, RA, RB**

Let the effective address (EA) be the sum (RA|0)+(RB).

The **icbt** instruction provides a hint that the program will probably soon execute code from the block containing the byte addressed by EA, and that the block containing the byte addressed by EA is to be loaded into the cache specified by the CT field. (See Section 4.3 of Book II.) If the CT field is set to a value not supported by the implementation, no operation is performed.

The hint is ignored if the block is Caching Inhibited.

This instruction treated as a **Load** (see Section 4.3), except that the system data storage error handler is not invoked, and reference and change recording need not be done.

**Special Registers Altered:**

None

---

**Programming Note**

Because the instruction is treated as a **Load**, the effective address is translated using translation resources that are used for data accesses, even though the block being invalidated was copied into the instruction cache based on translation resources used for instruction fetches (see Book III).
4.3.2 Data Cache Instructions

The Data Cache instructions control various aspects of the data cache.

**TH field in the dcbt and dcbtst instructions**

Described below are the TH field values for the `dcbt` and `dcbtst` instructions. For all TH field values which are not listed, the hint provided by the instruction is undefined.

**TH=0b00000**

If TH=0b00000, the `dcbt/dcbtst` instruction provides a hint that the program will probably soon access the block containing the byte addressed by EA.

**TH=0b00000 - 0b00111 [Category: Cache Specification]**

In addition to the hint specified above for the TH field value of 0b00000, an additional hint is provided indicating that placement of the block in the cache specified by the TH field might also improve performance. The correspondence between each value of the TH field and the cache to be specified is the same as the correspondence between each value the CT field and the cache to be specified as defined in Section 4.3. The hints corresponding to values of the TH field not supported by the implementation are undefined.

**TH=0b01000 - 0b01111 [Category: Stream]**

The `dcbt/dcbtst` instructions provide hints regarding a sequence of accesses to data elements, or indicate the expected use thereof. Such a sequence is called a “data stream”, and a `dcbt/dcbtst` instruction in which TH is set to one of these values is said to be a “data stream variant” of `dcbt/dcbtst`. In the remainder of this section, “data stream” may be abbreviated to “stream”.

A data stream to which a program may perform Load accesses is said to be a “load data stream”, and is described using the data stream variants of the `dcbt` instruction. A data stream to which a program may perform Store accesses is said to be a “store data stream”, and is described using the data stream variants of the `dcbtst` instruction.

When, and how often, effective addresses for a data stream are translated is implementation-dependent.

Each data element is associated with a unit of storage, which is the aligned 128-byte location in storage that contains the first byte of the element. The data stream variants may be used to specify the address of the beginning of the data stream, the displacement (stride) between the first byte of successive elements, and the number of unique units of storage that are associated with all of the data elements. If the stride is specified, both the stride and the address of the first element are specified at 4 byte granularity. If the stride is not specified, the address of the first element is the address of the first unit.

**Programming Note**

The architecture does not provide a way to specify the size of the data elements that compose a stream. An implementation may assume some fixed size for all data elements. As a result, depending on the offset, stride, and size (and in particular whether the elements are aligned), the implementation may reduce the latency for accessing only a portion of some of the elements. A future version of the architecture may enable the specification of element size to avoid this limitation.

**Bit(s) Description**

0:56 **EATRUNC**

High-order 57 bits of the effective address of the first element of the data stream. (i.e., the effective address of the first unit of the stream is `EATRUNC` | 70)

57 **Direction** (D)

0 Subsequent elements have increasing addresses.

1 Subsequent elements have decreasing addresses.
58  Unlimited/GO (UG)
    0  No information is provided by the UG field.
    1  The number of elements in the data stream is unlimited, the elements are adjacent to each other, the program's need for each element of the stream is not likely to be transient, and the program will probably soon access the stream.

59  Reserved
60:63  Stream ID (ID)
    Stream ID to use for this data stream.

01010  The dcbt/dcbtst instruction provides a hint that describes certain attributes of a data stream, or indicates that the program will probably soon access data streams that have been described using data stream variants of the dcbt/dcbtst instruction, or will probably no longer access such data streams.

The EA is interpreted as follows. If GO=1 and S≠0b00 the hint provided by the instruction is undefined; the remainder of this instruction description assumes that this combination is not used.

<table>
<thead>

Bit(s) Description

0:31  GO

32 0  No information is provided by the GO field.
   1  For dcbt, the program will probably soon access all nascent load and store data streams that have been completely described, and will probably no longer access all other nascent load and store data streams. All other fields of the EA are ignored. ("Nascent" and "completely described" are defined below.) For dcbtst, this field value holds no meaning and is treated as though it were zero.

33:34  Stop (S)

00  No information is provided by the S field.
   01  Reserved
   10  The program will probably no longer access the data stream (if any) associated with the specified stream ID. (All other fields of the EA except the ID field are ignored.)

11  For dcbt, the program will probably no longer access the load and store data streams associated with all stream IDs. (All other fields of the EA are ignored.) For dcbtst, this field value holds no meaning, and is treated as though it were 0b00.

35  Reserved
36:38  Depth (DEP)
    The DEP field provides a relative estimate of how many elements ahead of the point of stream use the latency-reducing actions should go. This value reflects a comparison of the rate of consumption of the elements of the data stream and the latency to bring an arbitrary element of the stream into cache. The values are as follows.

<p>| | | | | | | | |</p>

39:46  Reserved
47:56  UNITCNT
    Number of units in data stream.

57  Transient (T)
    If T=1, the program's need for each element of the data stream is likely to be transient (i.e., the time interval during which the program accesses the element is likely to be short).

58  Unlimited (U)
    If U=1, the number of units in the data stream is unlimited (and the UNITCNT field is ignored).

59  Reserved
60:63  Stream ID (ID)
    Stream ID to use for this data stream (GO=0 and S=0b00), or stream ID associated with the data stream which the program will probably no longer access (S=0b10).
Chapter 4. Storage Control Instructions

The `dcbt/dcbtst` instruction provides a hint that describes certain attributes of a data stream.

The EA is interpreted as follows.

<table>
<thead>
<tr>
<th>Bit(s) Description</th>
<th>Bit(s) Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:31 Reserved</td>
<td>32:49 Stride</td>
</tr>

</tr>
<tr>
<td></td>
<td>60:63 Stream ID (ID)</td>
</tr>
</tbody>
</table>

The number of elements ahead of the point of stream use indicated by a given depth value may differ across implementations, as may the latency to bring a given element into the cache. To achieve optimum performance, some experimentation with different depth values may be necessary.

A program should use a `dcbt/dcbtst` instruction with TH=0b01011 only when the stride is larger than 128 bytes. Otherwise, consecutive units will be accessed, so the additional stream information has no benefit.

If the specified stream ID value is greater than m-1, where m is the number of stream IDs provided by the implementation, and either (a) TH=0b01000 or TH=0b01011, or (b) TH=0b01010 with GO=0 and S=0b11, no hint is provided by the instruction.

The following terminology is used to describe the state of a data stream. Except as described in the paragraph after the next paragraph, the state of a data stream at a given time is determined by the most recently provided hint(s) for the stream.

- A data stream for which only descriptive hints have been provided (by `dcbt/dcbtst` instructions with TH=0b01000 and UG=0, TH=0b01010 and GO=0 and S=0b00, and/or with TH=0b01011) is said to be "nascent". A nascent data stream for which all relevant descriptive hints have been provided (by the `dcbt/dcbtst` usages listed in the preceding sentence) is considered to be "completely described". The order of descriptive hints with respect to one another is unimportant.

- A data stream for which a hint has been provided (by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=1 or `dcbt` with TH=0b01010 and S=0b00) that the program will probably soon access it is said to be "active".

- A data stream that is either nascent or active is considered to "exist".

- A data stream for which a hint has been provided (e.g., by a `dcbt` instruction with TH=0b01010 and S=0b00) that the program will probably no longer access it is considered no longer to exist.

The hint provided by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=1 implicitly includes a hint that the program will probably no longer access the data stream (if any) previously associated with the specified stream ID. The hint provided by a `dcbt/dcbtst` instruction with TH=0b01000 and UG=0, or with TH=0b01010 and GO=0 and S=0b00, or with TH=0b01011 implicitly includes a hint that the program will probably no longer access the active data stream (if any) previously associated with the specified stream ID.

If a data stream is specified without using a `dcbt/dcbtst` instruction with TH=0b01010 and GO=0 and S=0b00, then the number of elements in the stream is unlimited, and the program's need for each element of the stream is not likely to be transient. If a data stream is specified without using a `dcbt/dcbtst` instruction with
TH=0b01011, then the stream will access consecutive units of storage.

Interrupts (see Book III) cause all existing data streams to cease to exist. In addition, depending on the implementation, certain conditions and events may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a page.
To obtain the best performance across the widest range of implementations that support the data stream variants of `dcbt/dcbtst`, the programmer should assume the following model when using those variants.

- The processor's response to a hint that the program will probably soon access a given data stream is to take actions that reduce the latency of accesses to the first few elements of the stream. (Such actions may include prefetching cache blocks into levels of the storage hierarchy that are “near” the processor.) Thereafter, as the program accesses each successive element of the stream, the processor takes latency-reducing actions for additional elements of the stream, pacing these actions with the program's accesses (i.e., taking the actions for only a limited number of elements ahead of the element that the program is currently accessing).

The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, is to stop taking latency-reducing actions for the stream.

- A data stream having finite length ceases to exist when the latency-reducing actions have been taken for all elements of the stream.

- If the program ceases to need a given data stream before having accessed all elements of the stream (always the case for streams having unlimited length), performance may be improved if the program then provides a hint that it will no longer access the stream (e.g., by executing the appropriate `dcbt` instruction with \( TH=0b01010 \) and \( S\neq0b00 \)).

- At each level of the storage hierarchy that is “near” the processor, elements of a data stream that is specified as transient are most likely to be replaced. As a result, it may be desirable to stagger addresses of streams (choose addresses that map to different cache congruence classes) to reduce the likelihood that an element of a transient stream will be replaced prior to being accessed by the program.

- Processors that comply with versions of the architecture that do not support the TH field at all treat \( TH=0b01000, 0b01010, \) and \( 0b01011 \) as if \( TH=0b00000 \).

- A single set of stream IDs is shared between the `dcbt` and `dcbtst` instructions.

- On some implementations, data streams that are not specified by software may be detected by the processor. Such data streams are called “hardware-detected data streams”. On some such implementations, data stream resources (resources that are used primarily to support data streams) are shared between software-specified data streams and hardware-detected data streams. On these latter implementations, the programming model includes the following.

  - Software-specified data streams take precedence over hardware-detected data streams in use of data stream resources.

  - The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, includes releasing the associated data stream resources, so that they can be used by hardware-detected data streams.
Programming Note

The latency-reducing actions taken in response to a program's hints about access to a data stream, including the depth and urgency parameters, may vary based on its behavior and on the behavior of other programs sharing platform resources, as well as on the design of the platform resources they use. Without actually changing the stream specification or DSCR parameters, the processor may adjust its actions (e.g. slow down prefetches or be more selective choosing them) based on their effectiveness and on the availability of storage bandwidth. In general, the goal of this variation is to improve overall system performance and fairness across the set of programs that share resources. There often will be a performance benefit, however, from adjusting stream specifications to the platform and co-resident programs to adjust for these actions by the processor.
This Programming Note describes several aspects of using the data stream variants of the `dcbt` and `dcbtst` instructions.

- A non-transient data stream having unlimited length and which will access consecutive units in storage can be completely specified, including providing the hint that the program will probably soon access it, using one `dcbt` instruction. The corresponding specification for a data stream having other attributes requires two or three `dcbt/dcbtst` instructions to describe the stream and one additional `dcbt` instruction to start the stream. However, one `dcbt` instruction with TH=0b01010 and GO=1 can apply to a set of the data streams described in the preceding sentence, so the corresponding specification for n such data streams requires 2×n to 3×n `dcbt/dcbtst` instructions plus one `dcbt` instruction. (There is no need to execute a `dcbt/dcbtst` instruction with TH=0b01010 and S=0b10 for a given stream ID before using the stream ID for a new data stream; the implicit portion of the hint provided by `dcbt/dcbtst` instructions that describe data streams suffices.)

- If it is desired that the hint provided by a given `dcbt/dcbtst` instruction be provided in program order with respect to the hint provided by another `dcbt/dcbtst` instruction, the two instructions must be separated by an `eieio<S>` or `mbar<E>` instruction. For example, if a `dcbt` instruction with TH=0b01010 and GO=1 is intended to indicate that the program will probably soon access nascent data streams described (completely) by preceding `dcbt/dcbtst` instructions, and is intended not to indicate that the program will probably soon access nascent data streams described (completely) by following `dcbt/dcbtst` instructions, an `eieio<S>` or `mbar<E>` instruction must separate the `dcbt` instruction with GO=1 from the preceding `dcbt/dcbtst` instructions, and another `eieio<S>` or `mbar<E>` instruction must separate that `dcbt` instruction from the following `dcbt/dcbtst` instructions.

- In practice, the second `eieio<S>` or `mbar<E>` described above can sometimes be omitted. For example, if the program consists of an outer loop that contains the `dcbt/dcbtst` instructions and an inner loop that contains the `Load` or `Store` instructions that access the data streams, the characteristics of the inner loop and of the implementation's branch prediction mechanisms may make it highly unlikely that hints corresponding to a given iteration of the outer loop will be provided out of program order with respect to hints corresponding to the previous iteration of the outer loop. (Also, any providing of hints out of program order affects only performance, not program correctness.)

- To mitigate the effects of interrupts on data streams, it may be desirable to specify a given "logical" data stream as a sequence of shorter, component data streams. Similar considerations apply to conditions and events that, depending on the implementation, may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a virtual page.

- If it is desired to specify data streams without regard to the number of stream IDs provided by the implementation, stream IDs should be assigned to data streams in order of decreasing stream importance (stream ID 0 to the most important stream, stream ID 1 to the next most important stream, etc.). This order ensures that the hints for the most important data streams will be provided.

### TH=0b10000

If TH=0b10000, the `dcbt` instruction provides a hint that the program will probably soon load from the block containing the byte addressed by EA, and that the program's need for the block will be transient (i.e. the time interval during which the program accesses the block is likely to be short).

### TH=0b10001

If TH=0b10001, the `dcbt` instruction provides a hint that the program will probably not access the block containing the byte addressed by EA for a relatively long period of time.
Data Cache Block Allocate X-form

dcba RA,RB
[Category: Embedded]

Data Cache Block Touch X-form

dcbt RA,RB,TH [Category: Server]
dcbt TH,RA,RB [Category: Embedded]

Let the effective address (EA) be the sum (RA0)+(RB).

This instruction provides a hint that the program will probably soon store into a portion of the block and the contents of the rest of the block are not meaningful to the program. The contents of the block are undefined when the instruction completes. The hint is ignored if the block is Caching Inhibited.

This instruction is treated as a Store (see Section 4.3) except that the instruction is treated as a no-op if execution of the instruction would cause the system data storage error handler to be invoked.

Special Registers Altered:
None

Extended Mnemonics:

Extended mnemonics are provided for the Data Cache Block Touch instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

Extended: Equivalent to:
dcbtct RA,RB,TH dcbt for TH values of 0b00000 - 0b00111; other TH values are invalid.
dcbtds RA,RB,TH dcbt for TH values of 0b00000 or 0b01000 - 0b01111; other TH values are invalid.
dcbtt RA,RB dcbt for TH value of 0b10000
dcbna RA,RB dcbt for TH value of 0b10001
Data Cache Block Touch for Store X-form

dcbtst RA, RB, TH

dcbtst TH, RA, RB

Let the effective address (EA) be the sum (RA|0)+(RB).

The `dcbtst` instruction provides a hint that describes a block or data stream to which the program may perform a Store access, or indicates the expected use thereof. A hint that the program will soon store to a given storage location is ignored if the location is Caching Inhibited or Guarded.<S>

The only operation that is “caused by” the `dcbtst` instruction is the providing of the hint. The actions (if any) taken by the processor in response to the hint are not considered to be “caused by” or “associated with” the `dcbtst` instruction (e.g., `dcbtst` is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by memory barriers.

The `dcbtst` instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified at the beginning of this section. If TH≠0b01010 and TH≠0b01011, this instruction is treated as a Store (see Section 4.3), except that the system data storage error handler is not invoked, reference recording<S> need not be done, and change recording<S> is not done.

Special Registers Altered:
None

Extended Mnemonics:

Extended mnemonics are provided for the `Data Cache Block Touch for Store` instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

```
Extended:          Equivalent to:
dcbtstct RA, RB, TH  dcbtst for TH values of 0b00000
                   or 0b00000 - 0b00111;
                   other TH values are invalid.

dcbtstds RA, RB, TH   dcbtst for TH values of 0b00000
                   or 0b01000 - 0b01111;
                   other TH values are invalid.

dcbtstt RA, RB        dcbtst for TH value of 0b10000.
```

Programming Note

See the Programming Notes at the beginning of this section.
Data Cache Block set to Zero \quad X-form

dcbz \quad RA,RB

\begin{verbatim}
 0 31 ///  RA  RB   1014
 6

\end{verbatim}

if RA = 0 then \( b \leftarrow 0 \)
else \( b \leftarrow (RA) \)
EA \( \leftarrow b + (RB) \)
n \( \leftarrow \) block size (bytes)
m \( \leftarrow \log_2(n) \)
ea \( \leftarrow EA_{0:63-m} \mid 0 \)
MEM(ea, n) \( \leftarrow \) n0x00

Let the effective address (EA) be the sum (RA0)+(RB).

All bytes in the block containing the byte addressed by EA are set to zero.

This instruction is treated as a Store (see Section 4.3).

Special Registers Altered:

None

Programming Note

dcbz does not cause the block to exist in the data cache if the block is in storage that is Caching Inhibited.

For storage that is neither Write Through Required nor Caching Inhibited, dcbz provides an efficient means of setting blocks of storage to zero. It can be used to initialize large areas of such storage, in a manner that is likely to consume less memory bandwidth than an equivalent sequence of Store instructions.

For storage that is either Write Through Required or Caching Inhibited, dcbz is likely to take significantly longer to execute than an equivalent sequence of Store instructions. For example, on some implementations dcbz for such storage may cause the system alignment error handler to be invoked; on such implementations the system alignment error handler sets the specified block to zero using Store instructions.

See Section 5.9.1 of Book III-S and Section 6.11.1 of Book III-E for additional information about dcbz.
Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a Load (see Section 4.3), except that reference and change recording need not be done, and it is treated as a Write with respect to debug events.

Special Registers Altered:
None

Let the effective address (EA) be the sum (RA|0)+(RB).

L=0

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data caches of all processors.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data cache of this processor.

L=1 (“dcbf local”) [Category: Server, Embedded, Phased-In]

The L=1 form of the dcbf instruction permits a program to limit the scope of the “flush” operation to the data cache of this processor. If the block containing the byte addressed by EA is in the data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

L = 3 (“dcbf local primary”) [Category: Server, Embedded, Phased-In]

The L=3 form of the dcbf instruction permits a program to limit the scope of the “flush” operation to the primary data cache of this processor. If the block containing the byte addressed by EA is in the primary data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

For the L operand, the value 2 is reserved. The results of executing a dcbf instruction with L=2 are boundedly undefined.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.
This instruction is treated as a Load (see Section 4.3), except that reference and change recording need not be done, and it is treated as a Write with respect to debug events.

Special Registers Altered:
None

Extended Mnemonics:

Extended mnemonics are provided for the Data Cache Block Flush instruction so that it can be coded with the L value as part of the mnemonic rather than as a numeric operand. These are shown as examples with the instruction. See Appendix A, "Assembler Extended Mnemonics" on page 827. The extended mnemonics are shown below.

Extended:                      Equivalent to:
dcbf RA, RB                   dcbf RA, RB, 0
      dcbfl RA, RB              dcbf RA, RB, 1
      dcbflp RA, RB           dcbf RA, RB, 3

Except in the dcbf instruction description in this section, references to "dcbf" in Books I-III imply L=0 unless otherwise stated or obvious from context; "dcbfl" is used for L=1 and "dcbflp" is used for L=3.

Programming Note

dcbf serves as both a basic and an extended mnemonic. The Assembler will recognize a dcbf mnemonic with three operands as the basic form, and a dcbf mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.

Programming Note

Dcbf with L=1 can be used to provide a hint that a block in this processor's data cache will not be reused soon.

Dcbf with L=3 can be used to flush a block from the processor's primary data cache but reduce the latency of a subsequent access. For example, the block may be evicted from the primary data cache but a copy retained in a lower level of the cache hierarchy.

Programs which manage coherence in software must use dcbf with L=0.

4.3.2.1 Obsolete Data Cache Instructions [Category: Vector]

The Data Stream Touch (dstf), Data Stream Touch for Store (dstst), and Data Stream Stop (dss) instructions (primary opcode 31, extended opcodes 342, 374, and 822 respectively), which were proposed for addition to the Power ISA and were implemented by some processors, must be treated as no-ops (rather than as illegal instructions).

The treatment of these instructions is independent of whether other Vector instructions are available (i.e., is independent of the contents of MSRVEC<S> (see Book III-S) or MSRSPV (see Book III-E).

Programming Note

These instructions merely provided hints, and thus were permitted to be treated as no-ops even on processors that implemented them.

The treatment of these instructions is independent of whether other Vector instructions are available because, on processors that implemented the instructions, the instructions were available even when other Vector instructions were not.

The extended mnemonics for these instructions were dstt, dststt, and dssall.

4.3.3 “or” Instruction

“or” Cache Control Hint

or 26,26,26

This form of or provides a hint that stores caused by preceding Store and dcbz instructions should be performed with respect to other processors and mechanisms as soon as is feasible.
Extended Mnemonics:

Additional extended mnemonic for the or hint:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>miso</td>
<td>or 26,26,26</td>
</tr>
</tbody>
</table>

**Programming Note**

This form of the or instruction can be used to reduce latency in producer-consumer applications by requesting that modified data be made visible to other processors quickly.

**Producer:**

```assembly
addi r1, r1, 0x1234
sth r1, 0x1000(r0) # store data value 0x1234
addi r2, r2, 0x0001
stb r2, 0x1002(r0) # store nonzero flag byte
or r26, r26, r26  # miso
p_loop:
    lbz r2, 0x1002(r0)
    andi. r2, r2, 0x00FF
    bne p_loop        # wait for clear of flag byte
```

**Consumer:**

```assembly
c_loop:
    lbz r2, 0x1002(r0)
    andi. r2, r2, 0x00FF
    beq c_loop        # check for valid flag
    lbz r1, 0x1000(r0) # load data value
addi r2, r2, 0x0000
stb r2, 0x1002(r0) # clear valid flag
or r26, r26, r26  # miso
```

**Engineering Note**

Implementation of miso should attempt to order the hint relative to stores caused by preceding accesses. Implementations may elect to treat miso as a no-op.

Ways to implement miso include the following.

- In a store queue that has potentially different priorities for forwarding stores, the miso instruction could increase the priority of stores caused by preceding instructions.
- In a store queue that holds stores to allow for gathering, the miso instruction could release the hold and allow the stores to proceed to be performed with respect to other processors.

**Programming Note**

Warning: Other forms of or Rx,Rx,Rx that are not described in this section and in may also cause program priority to change. Use of these forms should be avoided except when software explicitly intends to alter program priority. If a no-op is needed, the preferred no-op (ori 0,0,0) should be used.
4.4 Synchronization Instructions

The synchronization instructions are used to ensure that certain instructions have completed before other instructions are initiated, or to control storage access ordering, or to support debug operations.

4.4.1 Instruction Synchronize Instruction

**Instruction Synchronize**

*XL-form*

isync

|   | 19 | 6 | 11 | 16 | 21 | 150 | 31 |

Executing an `isync` instruction ensures that all instructions preceding the `isync` instruction have completed before the `isync` instruction completes, and that no subsequent instructions are initiated until after the `isync` instruction completes. It also ensures that all instruction cache block invalidations caused by `icbi` instructions preceding the `isync` instruction have been performed with respect to the processor executing the `isync` instruction, and then causes any prefetched instructions to be discarded.

Except as described in the preceding sentence, the `isync` instruction may complete before storage accesses associated with instructions preceding the `isync` instruction have been performed.

This instruction is context synchronizing (see Book III).

**Special Registers Altered:**

None

4.4.2 Load and Reserve and Store Conditional Instructions

The *Load And Reserve* and *Store Conditional* instructions can be used to construct a sequence of instructions that appears to perform an atomic update operation on an aligned storage location. See Section 1.7.3, “Atomic Update” for additional information about these instructions.

The *Load And Reserve* and *Store Conditional* instructions are fixed-point *Storage Access* instructions; see Section 3.3.1, “Fixed-Point Storage Access Instructions”, in Book I.

The storage location specified by the *Load And Reserve* and *Store Conditional* instructions must be in storage that is Memory Coherence Required if the location may be modified by another processor or mechanism. If the specified location is in storage that is Write Through Required or Caching Inhibited, the system data storage error handler is invoked for the Server environment and may be invoked for the Embedded environment.

The *Load and Reserve* instructions include an Exclusive Access hint (EH), which can be used to indicate that the instruction sequence being executed is implementing one of two types of algorithms:

**Atomic Update (EH=0)**

This hint indicates that the program is using a fetch and operate (e.g., fetch and add) or some similar algorithm and that all programs accessing the shared variable are likely to use a similar operation to access the shared variable for some time.

**Exclusive Access (EH=1)**

This hint indicates that the program is attempting to acquire a lock and if it succeeds, will perform another store to the lock variable (releasing the lock) before another program attempts to modify the lock variable.

**Programming Note**

The Memory Coherence Required attribute on other processors and mechanisms ensures that their stores to the reservation granule will cause the reservation created by the *Load And Reserve* instruction to be lost.
Programming Note

Because the Load And Reserve and Store Conditional instructions have implementation dependencies (e.g., the granularity at which reservations are managed), they must be used with care. The operating system should provide system library programs that use these instructions to implement the high-level synchronization functions (Test and Set, Compare and Swap, locking, etc.; see Appendix B) that are needed by application programs. Application programs should use these library programs, rather than use the Load And Reserve and Store Conditional instructions directly.

Programming Note

EH = 1 should be used when the program is obtaining a lock variable which it will subsequently release before another program attempts to perform a store to it. When contention for a lock is significant, using this hint may reduce the number of times a cache block is transferred between processor caches.

EH = 0 should be used when all accesses to a mutex variable are performed using an instruction sequence with Load and Reserve followed by Store Conditional (e.g., emulating atomic update primitives such as "Fetch and Add;" see Appendix B). The processor may use this hint to optimize the cache to cache transfer of the block containing the mutex variable, thus reducing the latency of performing an operation such as ‘Fetch and Add’.

Programming Note

Either value of the EH field is appropriate for a Load and Reserve instruction that is intended to establish a reservation for a subsequent waitrsv and not a subsequent Store Conditional instruction.

Programming Note

Warning: On some processors that comply with versions of the architecture that precede Version 2.00, executing a Load And Reserve instruction in which EH = 1 will cause the illegal instruction error handler to be invoked.

Load Byte And Reserve Indexed X-form

[Category: Phased-In]

lbarx RT,RA,RB,EH

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

| 0  | 6  | 11 | 16 | 21 | 31 |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)

RESERVE ← 1
RESERVE_LENGTH ← 1
RESERVE_ADDR ← real_addr(EA)
RT ← $560 || MEM(EA, 1)

Let the effective address (EA) be the sum (RA|0)+(RB). The byte in storage addressed by EA is loaded into RT₅₆:₆₃. RT₀:₅₅ are set to 0.

This instruction creates a reservation for use by a stbcx instruction. A real address computed from the EA as described in Section 1.7.3.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 1 byte is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the byte in storage addressed by EA before some other processor attempts to modify it.

0 Other programs might attempt to modify the byte in storage addressed by EA regardless of the result of the corresponding stbcx instruction.
1 Other programs will not attempt to modify the byte in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

Special Registers Altered:
None

Programming Note

lbarx serves as both a basic and an extended mnemonic. The Assembler will recognize a lbarx mnemonic with four operands as the basic form, and a lbarx mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.
Load Halfword And Reserve Indexed X-form
[Category: Phased-In]

\[ \text{lharx } RT, RA, RB, EH \]

| if RA = 0 then b ← 0          
else                    b ← (RA)

| RESERVE_LENGTH ← 2      
| RESERVE_ADDR ← real_addr(EA)   
| RT ← 480 || MEM(EA, 2) |

Let the effective address (EA) be the sum (RA|0)+(RB).
The halfword in storage addressed by EA is loaded into RT48:63. RT0:47 are set to 0.

This instruction creates a reservation for use by a \text{sthcx}. instruction. A real address computed from the EA as described in Section 1.7.3.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 2 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the halfword in storage addressed by EA before some other processor attempts to modify it.

0 Other programs might attempt to modify the halfword in storage addressed by EA regardless of the result of the corresponding \text{sthcx}. instruction.
1 Other programs will not attempt to modify the halfword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 2. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

Special Registers Altered:
None

Programming Note
\text{lharx} serves as both a basic and an extended mnemonic. The Assembler will recognize a \text{lharx} mnemonic with four operands as the basic form, and a \text{lharx} mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

Load Word And Reserve Indexed X-form

\[ \text{lwarx } RT, RA, RB, EH \]

- else b ← (RA)
- EA ← b + (RB)
- RESERVE ← 1
- RESERVE_LENGTH ← 8
- RESERVE_ADDR ← real_addr(EA)
- RT ← MEM(EA, 8)

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into RT.

This instruction creates a reservation for use by a **stdcx**. instruction. A real address computed from the EA as described in Section 1.7.3.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 8 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the doubleword in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the doubleword in storage addressed by EA regardless of the result of the corresponding **stdcx** instruction.
- 1 Other programs will not attempt to modify the doubleword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 8. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**

None

#### Programming Note

**ldarx** serves as both a basic and an extended mnemonic. The Assembler will recognize a **ldarx** mnemonic with four operands as the basic form, and a **ldarx** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

---

    - undefined_case ← 0
    - store_performed ← 0
  - else
    - undefined_case ← 0
    - store_performed ← 0

Let the effective address (EA) be the sum (RA|0)+(RB). If a reservation exists, the length associated with the reservation is 8 bytes, and the real storage location specified by the **stdcx**. is the same as the real storage location specified by the **ldarx** instruction that established the reservation, (RS) is stored into the doubleword in storage addressed by EA.

If a reservation exists, the length associated with the reservation is 8 bytes, and the real storage location specified by the **stdcx**. is not the same as the real storage location specified by the **ldarx** instruction that established the reservation, the following applies.

- If the Store Conditional Page Mobility category is supported, the following applies. Let z denote a naturally aligned block of real storage whose size...
is the smallest real page size supported by the implementation. If the real storage location specified by the \texttt{stdcx} is in the same \texttt{z} as the real storage location specified by the \texttt{ldarx} instruction that established the reservation, it is undefined whether (RS) is stored into the doubleword in storage addressed by EA. Otherwise, no store is performed.

- If the Store Conditional Page Mobility category is not supported, it is undefined whether (RS) is stored into the doubleword in storage addressed by EA.

If a reservation exists and the length associated with the reservation is not 8 bytes, it is undefined whether (RS) is stored into the doubleword in storage addressed by EA.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. \(n\) is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether the store is performed, the value of \(n\) is undefined (and need not reflect whether the store was performed).

\[
\text{CR}0_{\text{LT GT EQ SO}} = 0b00 \| n \| \text{XER}{\text{SO}}
\]

The reservation is cleared.

EA must be a multiple of 8. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**
4.4.2.2 CR0 128-bit Load and Reserve Store Conditional Instructions [Category: Load/Store Quadword]

For **lqarx**, the quadword in storage addressed by EA is loaded into an even-odd pair of GPRs as follows. In big-endian mode, the even-numbered GPR is loaded with the doubleword from storage addressed by EA and the odd-numbered GPR is loaded with the doubleword addressed by EA+8. In little-endian mode, the even-numbered GPR is loaded with the byte-reversed doubleword from storage addressed by EA+8 and the odd-numbered GPR is loaded with the byte-reversed doubleword addressed by EA.

In the preferred form of the **Load Quadword** instruction RA ≠ RTp+1 and RB ≠ RTp+1.

For **stqcx**, the contents of an even-odd pair of GPRs is stored into the quadword in storage addressed by EA as follows. In big-endian mode, the even-numbered GPR is stored into the doubleword in storage addressed by EA and the odd-numbered GPR is stored into the doubleword addressed by EA+8. In little-endian mode, the even-numbered GPR is stored byte-reversed into the doubleword in storage addressed by EA+8 and the odd-numbered GPR is stored byte-reversed into the doubleword addressed by EA.

### Load Quadword And Reserve Indexed X-form

**lqarx** RTp,RA,RB,EH

<table>
<thead>

<td>RB</td>
<td>RA</td>
<td>RB</td>
<td>RA</td>
<td>RA</td>
</tr>
</tbody>
</table>

if RA = 0 then b ← 0 else b ← (RA)
EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 16
RESERVE_ADDR ← real_addr(EA)
RTp ← MEM(EA, 16)

Let the effective address (EA) be the sum (RA|0)+(RB).
The quadword in storage addressed by EA is loaded into RTp.

This instruction creates a reservation for use by a **stqcx** instruction. A real address computed from the EA as described in Section 1.7.3.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 16 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the doubleword in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the doubleword in storage addressed by EA regardless of the result of the corresponding **stqcx** instruction.
- 1 Other programs will not attempt to modify the doubleword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 16. If it is not, the system alignment error handler is invoked.

If RTp is odd, RTp=RA, or RTp=RB the instruction form is invalid. If RTp=RA or RTp=RB, an attempt to execute this instruction will invoke the system illegal instruction error handler. (The RTp=RA case includes the case of RTp=RA=0.)

**Special Registers Altered:**
None

--- Programming Note ---

**lqarx** serves as both a basic and an extended mnemonic. The Assembler will recognize a **lqarx** mnemonic with four operands as the basic form, and a **lqarx** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.
Store Quadword Conditional Indexed X-form

CR0 \( \leftarrow 0b00 \mid \mid u2 \mid \mid XER_{SO} \)

else
  CR0 \( \leftarrow 0b00 \mid \mid \text{store_performed} \mid \mid XER_{SO} \)
RESERVE \( \leftarrow 0 \)

Let the effective address (EA) be the sum (RAI0)+(RB).

If a reservation exists, the length associated with the reservation is 16 bytes, and the real storage location specified by the \textit{stqcx.} is the same as the real storage location specified by the \textit{lqarx} instruction that established the reservation, (RSp) is stored into the quadword in storage addressed by EA.

If a reservation exists, the length associated with the reservation is 16 bytes, and the real storage location specified by the \textit{stqcx.} is not the same as the real storage location specified by the \textit{lqarx} instruction that established the reservation, it is undefined whether (RSp) is stored into the quadword in storage addressed by EA. Otherwise, no store is performed.

- If the Store Conditional Page Mobility category is not supported, it is undefined whether (RSp) is stored into the quadword in storage addressed by EA.

If a reservation exists and the length associated with the reservation is not 16 bytes, it is undefined whether (RSp) is stored into the quadword in storage addressed by EA.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. \( n \) is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether the store is performed, the value of \( n \) is undefined (and need not reflect whether the store was performed).

\[ \text{CR0}_{LT \ GT \ EQ \ SO} = 0b00 \ll n \ll XER_{SO} \]

The reservation is cleared.

EA must be a multiple of 16. If it is not, the system alignment error handler is invoked.

If RSp is odd, the instruction form is invalid.

Special Registers Altered:

CR0
4.4.3 Memory Barrier Instructions

The Memory Barrier instructions can be used to control the order in which storage accesses are performed. See Section 1.8, “Transactions [Category: Transactional Memory]” for a description of how the Memory Barrier instructions interact with transactions. Additional information about these instructions and about related aspects of storage management can be found in Book III.

Extended mnemonics for Synchronize

Extended mnemonics are provided for the Synchronize instruction so that it can be supported by assemblers that recognize only the msync<E> mnemonic and so that it can be coded with the L value as part of the mnemonic rather than as a numeric operand. These are shown as examples with the instruction. See Appendix A, “Assembler Extended Mnemonics” on page 827. The only reason for the msync<E> mnemonic is compatibility with Book E assembler code.

<td>6 9 11 12 16 21 31</td>
</tr>
</tbody>
</table>

if E ≠ 0b0000 then
  if E = 0b1xxxx then enforce_barrier(mbll)
  if E = 0bx1xx then enforce_barrier(mbls)
  if E = 0bxx1x then enforce_barrier(mbsl)
  if E = 0bxxx1 then enforce_barrier(mbss)
else
  switch(L)
  case(0): hwsync
  case(1): lwsync
  case(2): ptesync<S> or hwsync<E>

The sync instruction creates a memory barrier (see Section 1.7.1). The set of storage accesses that is ordered by the memory barrier depends on the value of the E and L fields. If the implementation supports the Elemental Memory Barriers category and the E field is nonzero, the L field is ignored as long as the E and L values do not create an invalid form (see Figure 4).

E=0 [Category: Elemental Barriers]

The memory barrier provides an ordering function for one or more distinct pairings of accesses to storage that is memory Coherence Required and is neither Write Through Required nor Caching Inhibited. Each bit in the E field that has a value of 1 selects pairings, as described below.

- E0=1 (mbll)
  The “load load” memory barrier is provided. Applicable pairs are all pairs a,b of such accesses in which a is an access caused by a Load instruction and b is an access caused by a Store or dcbz instruction.

- E1=1 (mbls)
  The “load store” memory barrier is provided. Applicable pairs are all pairs a,b of such accesses in which a is an access caused by a Load instruction and b is an access caused by a Store or dcbz instruction.

- E2=1 (mbsl)
  The “store load” memory barrier is provided. Applicable pairs are all pairs a,b of such accesses in which a is an access caused by a Store or dcbz instruction and b is an access caused by a Load instruction.

- E3=1 (mbss)
  The “store store” memory barrier is provided. Applicable pairs are all pairs a,b of such accesses in which both a and b are accesses caused by a Store or dcbz instruction.

L=0 (“heavyweight sync”)

The memory barrier provides an ordering function for the storage accesses associated with all instructions that are executed by the processor executing the sync instruction. The applicable pairs are all pairs a,b of storage accesses in which b is a data access, except that if a is the storage access caused by an icbi instruction then b may be performed with respect to the processor executing the sync instruction before a is performed with respect to that processor.

L=1 (“lightweight sync”)

The memory barrier provides an ordering function for the storage accesses caused by Load, Store, and dcbz instructions that are executed by the processor executing the sync instruction and for which the specified storage location is in storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited. The applicable pairs are all pairs a,b of storage accesses except those in which a is an access caused by a Store or dcbz instruction and b is an access caused by a Load instruction.

L=2<S> (“ptesync”)

The set of storage accesses that is ordered by the memory barrier is described in Section 5.9.2 of
Book III-S, as are additional properties of the `sync` instruction with L=2.

The ordering done by the memory barrier is cumulative (regardless of the E and L values).

If L=0 (or L=2), the `sync` instruction has the following additional properties.

- Executing the `sync` instruction ensures that all instructions preceding the `sync` instruction have completed before the `sync` instruction completes, and that no subsequent instructions are initiated until after the `sync` instruction completes.
- The `sync` instruction is execution synchronizing (see Book III). However, address translation and reference and change recording (see Book III) associated with subsequent instructions may be performed before the `sync` instruction completes.
- The memory barrier provides the additional ordering function such that if a given instruction that is the result of a store in set B is executed, all applicable storage accesses in set A have been performed with respect to the processor executing the instruction to the extent required by the associated memory coherence properties. The single exception is that any storage access in set A that is caused by an `icbi` instruction executed by the processor executing the `sync` instruction (P1) may not have been performed with respect to P1 (see the description of the `icbi` instruction on page 762).

The cumulative properties of the barrier apply to the execution of the given instruction as they would to a load that returned a value that was the result of a store in set B.

The value L=3 is reserved.

Figure 4 shows the valid encodings of the E and L fields, as well as the resulting memory barrier for systems that support the Elemental Memory Barriers category and those that do not.

---

**Programming Note**

In Figure 4, encodings in which E₂=1 also have L=0 (`hwsync`) to ensure backward compatibility.

---

**Assembler Note**

Combinations of E and L values other than those shown in Figure 4 should be flagged as errors.
The sync instruction may complete before storage accesses associated with instructions preceding the sync instruction have been performed.

See Section 6.11.3 of Book III-E for additional information related to sync with L=0 for the Embedded environment.

Special Registers Altered:
None

Extended Mnemonics:

Extended mnemonics for Synchronize:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>

</tbody>
</table>

Excerpt in the sync instruction description in this section, references to “sync” in Books I-III imply L=0 unless otherwise stated or obvious from context; the appropriate extended mnemonics are used when other L values are intended. Throughout Books I-III, references to the L field imply E=0b0000 unless otherwise stated or obvious from context; the E field is mentioned explicitly when other E values are intended. Some programming examples and recommendations assume a common programming model that does not include the Elemental Memory Barriers category. Improved performance may be achieved through the use of elemental memory barriers in many cases.

Programming Note

Section 1.9 contains a detailed description of how to modify instructions such that a well-defined result is obtained.

Programming Note

sync serves as both a basic and an extended mnemonic. The Assembler will recognize a sync mnemonic with one operand as the basic form, and a sync mnemonic with no operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.
The sync instruction can be used to ensure that all stores into a data structure, caused by Store instructions executed in a “critical section” of a program, will be performed with respect to another processor before the store that releases the lock is performed with respect to that processor; see Section B.2, “Lock Acquisition and Release, and Related Techniques” on page 831.

The memory barrier created by a sync instruction with L=1 does not order implicit storage accesses or instruction fetches. The memory barrier created by a sync instruction with L=0 (or L=2) orders implicit storage accesses and instruction fetches associated with instructions preceding the sync instruction but not those associated with instructions following the sync instruction.

In order to obtain the best performance across the widest range of implementations, the programmer should use the sync instruction with L=1, or the eleio<sub>S</sub> or mbar<sub>E</sub> instruction, if any of these is sufficient for his needs; otherwise he should use sync with L=0. sync with L=2<sub>S</sub> should not be used by application programs.

The functions provided by sync with L=1 are a strict subset of those provided by sync with L=0. (The functions provided by sync with L=2<sub>S</sub> are a strict superset of those provided by sync with L=0; see Book III.)
Enforce In-order Execution of I/O  X-form

eieio

[Category: Server]

<table>
<thead>
<tr>
<th>31</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>21</th>
<th>854</th>
<th>/</th>
</tr>
</thead>
</table>

The *eieio* instruction creates a memory barrier (see Section 1.7.1, “Storage Access Ordering”), which provides an ordering function for the storage accesses caused by *Load*, *Store*, *dcbez*, *eciwx*, and *ecowx* instructions executed by the processor executing the *eieio* instruction. These storage accesses are divided into the two sets listed below. The storage access caused by an *eciwx* instruction is ordered as a load, and the storage access caused by a *dcbez* or *ecowx* instruction is ordered as a store.

1. Loads and stores to storage that is both Caching Inhibited and Guarded, and stores to main storage caused by stores to storage that is Write Through Required.

   The applicable pairs are all pairs $a_i, b_j$ of such accesses.

2. Stores to storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited.

   The applicable pairs are all pairs $a_i, b_j$ of such accesses.

The operations caused by the stream variants of the *dcbt* and *dcbtst* instructions (i.e. the providing of hints) are ordered by *eieio* as a third set of operations, and the operations caused by *tibie* and *tibsinc* instructions (see Book III-S) are ordered by *eieio* as a fourth set of operations.

Each of the four sets of storage accesses or operations is ordered independently of the other three sets. The ordering done by *eieio*’s memory barrier for the second set is cumulative; the ordering done by *eieio*’s memory barrier for the other three sets is not cumulative.

The *eieio* instruction may complete before storage accesses associated with instructions preceding the *eieio* instruction have been performed. The *eieio* instruction may complete before operations caused by *dcbt* and *dcbtst* instructions preceding the sync instruction have been performed.

Special Registers Altered:

Memory Barrier  X-form

mbar  MO

[Category: Embedded]

<table>
<thead>
<tr>
<th>31</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>21</th>
<th>854</th>
<th>/</th>
</tr>
</thead>
</table>

When MO=0, the *mbar* instruction creates a cumulative memory barrier (see Section 1.7.1, “Storage Access Ordering”), which provides an ordering function for the storage accesses executed by the processor executing the *mbar* instruction.

When MO≠0, an implementation may support the *mbar* instruction ordering a particular subset of storage accesses. An implementation may also support multiple, non-zero values of MO that each specify a different subset of storage accesses that are ordered by the *mbar* instruction. Which subsets of storage accesses that are ordered and which values of MO that specify these subsets is implementation-dependent.

The *mbar* instruction may complete before storage accesses associated with instructions preceding the *mbar* instruction have been performed. The *mbar* instruction may complete before operations caused by *dcbt* and *dcbtst* instructions preceding the sync instruction have been performed.

Special Registers Altered:

None

---

Programming Note

The *eieio*<S> and *mbar*<E> instructions are intended for use in doing memory-mapped I/O. Because loads, and separately stores, to storage that is both Caching Inhibited and Guarded are performed in program order (see Section 1.7.1, “Storage Access Ordering” on page 742), *eieio*<S> or *mbar*<E> is needed for such storage only when loads must be ordered with respect to stores.

For the *eieio*<S> instruction, accesses in set 1, $a_i$ and $b_j$ need not be the same kind of access or be to storage having the same storage control attributes. For example, $a_i$ can be a load to Caching Inhibited, Guarded storage, and $b_j$ a store to Write Through Required storage.

If stronger ordering is desired than that provided by *eieio*<S> or *mbar*<E>, the *sync* instruction must be used, with the appropriate value in the L field.

---

Power ISA™ - Book II
4.4.4 Wait Instruction

The wait instruction allows instruction fetching and execution to be suspended under certain conditions, depending on the value of the WC field. A **wait** instruction without the WC field is treated as a **wait** instruction with WC=0.

The defined values for WC are as follows.

- **0b00** Resume instruction fetching and execution when an interrupt occurs.
- **0b01** Resume instruction fetching and execution when an interrupt occurs or when a reservation made by the processor does not exist (see Section 1.7.3). It is implementation-dependent whether this WC value is supported or **wait** with this WC value is treated as a no-op.
- **0b10** Resume instruction fetching and execution when an interrupt occurs or when an implementation-specific condition exists. It is implementation-dependent whether this WC value is supported or is treated as reserved.
- **0b11** This WC value is treated as a no-op.

If WC=0, or if WC=1 and a reservation made by the processor exists when the wait instruction is executed, or if WC=2 and the associated implementation-specific condition does not exist when the **wait** instruction is executed, the following applies:

- Instruction fetching and execution is suspended.
- Once the **wait** instruction has completed, the NIA will point to the next sequential instruction.
- Instruction fetching and execution resumes when any of the following conditions are met.
  - An interrupt occurs.
  - WC=1 and a reservation made by the processor does not exist.
  - WC=2 and the associated implementation-specific condition exists.

---

Programming Note

The functions provided by **eieio**<S> for its second set are a strict subset of those provided by **sync** with L=1.

Since **eieio**<S> and **mbar**<E> share the same op-code, software designed for both Server and Embedded environments must assume that only the **eieio**<S> functionality applies since the functions provided by **eieio** are a subset of those provided by **mbar** with MO=0.
When the wait instruction is executed, if WC=1 and a reservation made by the processor does not exist, or if WC=2 and the associated implementation-specific condition exists, the instruction is treated as a no-op.

**Programming Note**
On implementations which do not support the wait instruction with WC=0b10, the behavior for non-support (treated as reserved) differs from the non-support of the other non-zero WC values (treated as no-ops). The possibility of boundedly undefined behavior such as causing the system illegal instruction error handler to be invoked is meant to discourage the use of WC=0b10 in programs that are intended to be portable.

Only programs that are implementation-aware should use WC=0b10.

**Engineering Note**
Causing the system illegal instruction error handler to be invoked if an attempt is made to execute wait with WC=0b10 on an implementation that does not support that form of wait facilitates the debugging of software.

**Special Registers Altered:**
None

**Extended Mnemonics:**
Examples of extended mnemonics for Wait:

<table>
<thead>
<tr>
<th>Extended</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>wait</td>
<td>wait 0</td>
</tr>
<tr>
<td>waitrsv</td>
<td>wait 1</td>
</tr>
<tr>
<td>waitimpl</td>
<td>wait 2</td>
</tr>
</tbody>
</table>

**Programming Note**
The wait instruction with WC=0b00 can be used in verification test cases to signal the end of a test case. The encoding for the instruction is the same in both Big-Endian and Little-Endian modes.

**Programming Note**
The wait instruction may be useful as the primary instruction of an “idle process” or the completion of processing for a cooperative processor. However, overall system performance may be better served if the wait instruction is used by applications only for idle times that are expected to be short.

**Engineering Note**
In previous versions of the architecture the wait instruction was context synchronizing.
The *wait* instruction is not execution synchronizing and does not cause a memory barrier. *waitrsv* behavior relative to a preceding *Load and Reserve* instruction or *Store Conditional* instruction has a data dependency on the reservation. When execution proceeds past *waitrsv* as the result of another processor storing to the reservation granule, a subsequent load from the same storage location may return stale data. It is also possible that execution could proceed past the *waitrsv* for other reasons such as the occurrence of an interrupt. There are no architecturally defined means to determine what terminated the *wait*. Moreover, even if software were to attempt to determine what caused the *wait* to terminate, by the time the check occurred, both causes (interrupt and storage modification) might be true. Software must be designed to deal with the various causes of *wait* termination. In general, if the program that performed *wait* does not see the new value of the storage location for which the reservation was held, it should re-establish the reservation by repeating the *Load and Reserve* instruction, and then perform another *waitrsv*.

The following code waits for a device to update a memory location and assumes that r3 contains the address of the word to be updated. This assumes that software has already set this word to zero and is waiting for the device to update the word to a non-zero value.

```
loop:
    lwarx r4,0,r3 # load and reserve
    cmpwi r4,0    # exit if nonzero
    bne- exit
    waitrsv      # wait for reservation loss
    b loop
exit: ...
```

The *b* instruction results in re-execution of the *waitrsv* if instruction execution had resumed for some reason other than loss of the reservation made by the processor. This branch instruction is also necessary because the reservation might have been lost for reasons other than the device updating the memory location addressed by r3. Also, even if the device updated this memory location, the *lwarx* and *waitrsv* instructions may need to be re-executed until the *lwarx* returns the current data.

---

**Programming Note**

A *wait* instruction without the WC field is treated as a *wait* instruction with WC=0b00 because older processors that comply with Power ISA 2.06 do not support the WC field.
Chapter 5. Transactional Memory Facility [Category: Transactional Memory]

5.1 Transactional Memory Facility Overview

This chapter describes the registers and instructions that make up the transactional memory (TM) facility. Transactional memory is a shared-memory synchronization construct allowing an application to perform a sequence of storage accesses that appear to occur atomically with respect to other threads.

A set of instructions, special-purpose registers, and state bits in the MSR (see Book III) are used to control a transactional facility that is associated with each hardware thread. A \texttt{tbegin}. instruction is used to initiate transactional execution, and a \texttt{tend}. instruction is used to terminate transactional execution. Loads and stores that occur between the \texttt{tbegin}. and \texttt{tend}. instructions appear to occur atomically. An implementation may prematurely terminate transactional execution for a variety of reasons, rolling back all transactional storage updates that have been made by the thread since the \texttt{tbegin}. was executed, and rolling back the contents of a subset of the thread’s Book I registers to their contents before the \texttt{tbegin}. was executed. In the event of such premature termination, control is transferred to a software failure handler associated with the transaction, which may then retry the transaction or choose an alternate path depending on the cause of transaction failure. A transaction can be explicitly aborted via a set of \texttt{conditional abort} instructions and an \texttt{unconditional abort} instruction, \texttt{tabort}. A \texttt{tsr}. instruction is used to suspend or resume transactional execution, while allowing the transaction to remain active.

---

Programming Note

A \texttt{tbegin}. should always be followed immediately by a \texttt{beq} as the first instruction of the failure handler, that branches to the main body of the failure handler. The failure handler should always either retry the transaction or use non-transactional code to perform the same operation. (The number of retries should be limited to avoid the possibility of an infinite loop. The limit could be based on the perceived permanence / transience of the failure.)

A failure handler policy which includes trying a different transaction before returning to the one that failed may fail to make forward progress.

---

Programming Note

In code that may be executed transactionally, conditional branches should hint in favor of successful transactional execution where such a distinction exists. For example, the branch immediately following \texttt{tbegin}. should hint that the branch is very likely not to be taken. As another example, consider a method of coding a failure handler that executes the body of a transaction non-transactionally by branching past the TM control instructions (e.g. \texttt{tsuspend}). Branches that bypass the TM control instructions should also hint that the branch is very likely not to be taken. These predictions will improve the efficiency of transactional execution, and may also help prevent the addition of spurious accesses to the transactional footprint.
Transactions performed using this facility are “strongly atomic,” meaning that they appear atomic with respect to both transactional and non-transactional accesses performed by other threads. Transactions are isolated from reads and writes performed by other threads; i.e., transactional reads and writes will not appear to be interleaved with the reads and writes of other threads.

Nesting of transactions is supported using a form of nesting called “flattened nesting,” in which transactions that are initiated during transactional execution are subsumed by the pre-existing transaction. Consequently, the effects of a nested transaction do not become visible until the outer transaction commits, and if a nested transaction fails, the entire set of transactions (outer as well as nested) is rolled back, and control is transferred to the outer transaction’s failure handler. The memory barriers created by `tbegin`, and `tend`, and the integrated cumulative memory barrier that are described in Section 1.8, “Transactions [Category: Transactional Memory]” are only created for outer transactions and not for any transactions nested within them.

References to `Store` instructions, and stores, include `dcbz` and the storage accesses that it causes.

Rollback-Only Transactions

Rollback-Only Transactions (ROTs) differ from normal transactions in that they are speculative but not atomic. They may be nested with other ROTs or with normal transactions. When a normal transaction is initiated within a ROT, the behavior from the normal `tbegin`, until the end of the outer transaction is characteristic of a normal transaction. Although subject to failure from storage conflicts, the typical cause of ROT failure is via a `Tabort` variant that is executed after the program detects an error in its (software) speculation. Except where specifically differentiated or where differences follow from specific differentiation, the following description applies to ROTs as well as normal transactions.

5.1.1 Definitions

Commit: A transaction is said to commit when it successfully completes execution. When a transaction is committed, its transactional accesses become irrevocable, and are made visible to other threads. A transaction completes by either committing or failing.

Checkpointed registers: The set of registers that are saved to the “checkpoint area” when a transaction is initiated, and restored upon transaction failure, is a subset of the architected register state, consisting of the General Purpose Registers, Floating-Point Registers, Vector Registers, Vector-Scalar Registers, and the following Special Registers and fields: CR fields other than CR0, LR, CTR, FPSCR, AMR, PPR, VRSAVE, VSCR, DSCR, and TAR. The checkpointed registers include all problem-state writable registers with the exception of CR0, EBBHR, EBBRR, BESCR, the performance monitor registers, and the Transactional Memory registers. With the exception of updates of CR0, and the Transactional Memory registers, explicit updates of registers that are not included in the set of checkpointed registers are disallowed in Transactional state (i.e. will cause the transaction to fail), but are permitted in Suspended state. Suspended state modifications of these registers will not be rolled back in the event of transaction failure. (Modifications of Transactional Memory registers are only permitted in Non-transactional state. Attempts to modify Transactional Memory registers in other than Non-transactional state will cause a TM Bad Thing type Program interrupt.)

CR0, and the Transactional Memory registers (TFHAR, TEXASR, TFIAR) are not saved, or restored when the transaction fails, because they are modified as a side effect of transaction failure (so restoring them would lose information needed by the failure handler). The performance monitor registers, and the event-based branching registers (BESCR, EBBHR, EBBRR) are not saved or restored because saving and restoring them would add significant implementation complexity and is not needed by software. Also, these registers, except EBBHR, can be modified asynchronously by the processor, so restoring them when the transaction fails could cause loss of information.

Transactional accesses: Data accesses that are caused by an instruction that is executed when the thread is in the Transactional state (see Section 5.2) are said to be “transactional,” or to have been “performed transactionally.” The set of accesses caused by a committed normal transaction is performed as if it were a single atomic access. That is, it is always performed in its entirety with no visible fragmentation. The sets performed by normal transactions are thus serialized: each happens in its entirety in some order, even
when that order is not specified in the program or enforced between processors. Until a transaction commits, its set of transactional accesses is provisional, and will be discarded should the transaction fail. The set of transactional accesses is also referred to as the “transactional footprint.”

**Non-transactional accesses**: Storage accesses performed in the existing Power storage model are said to be “non-transactional.” In contrast to transactional storage accesses, there is no provision of atomicity across multiple non-transactional accesses. Non-transactional storage updates are not discarded in the event of a transaction failure.

**Outer transaction**: A transaction that is initiated from the Non-transactional state is said to be an outer transaction. A `tbegin` instruction that initiates an outer transaction is sometimes referred to as an “outer `tbegin`.” Similarly, a `tend` instruction with A=0 that ends an outer transaction is sometimes referred to as an “outer `tend`.”

**Nested Transaction**: A transaction that is initiated while already executing a transaction is said to be “nested” within the pre-existing transaction. The set of active nested transactions forms a stack growing from the outer transaction. A `tend` with A=0 will remove the most recently nested transaction from the stack.

**Failure**: A transaction failure is an exceptional condition causing the transactional footprint to be discarded, the checkpointed registers to be reverted to their pre-transactional values, and the failure handler to get control.

**Failure handler**: A failure handler is a software component responsible for handling transaction failure. On transaction failure, hardware redirects control to the failure handler associated with the outer transaction.

**Conflict**: A transactional memory access is said to conflict with another transactional or non-transactional access if both accesses reference the same cache block, and at least one of them is a store. If two transactions make conflicting accesses, at least one of them will fail. If a transaction fails as a result of a conflict with a store, the store may have been executed by another processor or may have been executed in Suspended state by the processor with the failing transaction. For a ROT, no conflict is caused if the ROT performs a load and another program performs a non-transactional store to the same block.

A transactional memory access is said to conflict with a `tlbie` if the storage location being accessed is in the page the translation for which is being invalidated by the tlbie. For a ROT, no conflict is caused if the access is a load.

A Suspended state cache control instruction is said to cause a conflict if it would cause the destruction of a transactional update or if it would make a transactional update visible to another thread.

---

### 5.2 Transactional Memory Facility States

The transactional memory facility supports several modes of operation, referred to in this document as the “transaction state.” These states control the behavior of storage accesses made during the transaction and the handling of transaction failure. Changes to transaction state affect all transactions currently using the transactional facility on the affected thread: the outer transaction as well as any nested transactions, should they exist.

**Non-transactional**: The default, initial state of execution; no transaction is executing. The transactional facility is available for the initiation of a new transaction.

**Transactional**: This state is initiated by the execution of a `tbegin` instruction in the Non-transactional state. Storage accesses (data accesses) caused by instructions executed in the Transactional state are performed transactionally. Other storage accesses associated with instructions executed in the Transactional state (instruction fetches, implicit accesses) are performed non-transactionally. In the event of transaction failure, failure is recorded as defined in Section 5.3.2, and control is transferred to the failure handler as described in Section 5.3.3.

**Suspended**: The Suspended execution state is explicitly entered with the execution of a `tsuspend` form of `tsr` instruction during a transaction, the execution of a `trechkpt` instruction from Non-transactional state, or as a side-effect of an interrupt while in the Transactional state. Storage accesses and accesses to SPRs that are not part of the checkpointed registers are performed non-transactionally; they will be performed independently of the outcome of the transaction. The initiation of a new transaction is prevented in this state. In the event of transaction failure, failure recording is performed as defined in Section 5.3.2, but failure handling is usually deferred until transactional execution is resumed (see Section 5.3.3 for details).

Until failure occurs, `Load` instructions that access storage locations that were transactionally written by the same thread will return the transactionally written data. After failure is detected, but before failure handling is performed, such loads may return either the transactionally written data, or the current non-transactional contents of the accessed location. The `tcheck` instruction can be used to determine whether any previous such loads may have returned non-transactional contents.

Suspended state `Store` instructions that access cache blocks that have been accessed transactionally (due to load or store) by the same thread may cause the transaction to fail.
Table 1 enumerates the set of Transactional Memory instructions and events that can cause changes to the transaction state. Transaction states are abbreviated N (Non-transactional), T (Transactional), and S (Suspended). (Interrupts, and the \texttt{rfebb}, \texttt{rfid}, \texttt{hrfid}, and \texttt{mtmsrd} instructions, can also cause changes to the transaction state; see Book III.)

The intent of the Suspended execution state is to temporarily escape from transactional handling when transactional semantics are undesirable. Examples of such cases include storage updates that should be retained in the event of transactional failure, which is useful for debugging, interthread communication, the access of Caching-Inhibited storage, and the handling of interrupts. In the event of transaction failure during the Suspended execution state, failure handling is deferred until transactional execution is resumed, allowing the block of Suspended state code to complete its activities.

During Suspended state execution, accessing cache blocks that have been transactionally accessed by the same thread prior to entering Suspended state requires special care, because failure may occur due to uncontrollable events such as interactions with other threads or the operating system. Up until a transaction fails, loads from transactionally modified cache blocks will return the transactionally modified data. However once the transaction fails, the loads may return either the transactionally updated version of storage, or the most recent non-transactional version. Stores to transactionally modified blocks may or may not cause the thread's transaction to fail.

Table 1 enumerates the set of Transactional Memory instructions and events that can cause changes to the transaction state. Transaction states are abbreviated N (Non-transactional), T (Transactional), and S (Suspended). (Interrupts, and the \texttt{rfebb}, \texttt{rfid}, \texttt{hrfid}, and \texttt{mtmsrd} instructions, can also cause changes to the transaction state; see Book III.)

\textbf{Programming Note}

The intent of the Suspended execution state is to temporarily escape from transactional handling when transactional semantics are undesirable. Examples of such cases include storage updates that should be retained in the event of transactional failure, which is useful for debugging, interthread communication, the access of Caching-Inhibited storage, and the handling of interrupts. In the event of transaction failure during the Suspended execution state, failure handling is deferred until transactional execution is resumed, allowing the block of Suspended state code to complete its activities.

During Suspended state execution, accessing cache blocks that have been transactionally accessed by the same thread prior to entering Suspended state requires special care, because failure may occur due to uncontrollable events such as interactions with other threads or the operating system. Up until a transaction fails, loads from transactionally modified cache blocks will return the transactionally modified data. However once the transaction fails, the loads may return either the transactionally updated version of storage, or the most recent non-transactional version. Stores to transactionally modified blocks may or may not cause the thread's transaction to fail.

Table 1 enumerates the set of Transactional Memory instructions and events that can cause changes to the transaction state. Transaction states are abbreviated N (Non-transactional), T (Transactional), and S (Suspended). (Interrupts, and the \texttt{rfebb}, \texttt{rfid}, \texttt{hrfid}, and \texttt{mtmsrd} instructions, can also cause changes to the transaction state; see Book III.)

\textbf{Programming Note}

\texttt{tbegin}. in Suspended state merely updates CR0. When \texttt{tbegin}. is followed by \texttt{beq}. this will result in a transfer to the failure handler. Nothing more severe (e.g. an interrupt) is required. The failure handler for a transaction for which initiation may be attempted in Suspended state should test CR0 to determine whether \texttt{tbegin}. was executed in Suspended state. If so, it should attempt to emulate the transaction non-transactionally. (This case can arise, for example, if a transaction enters Suspended state and then calls a library routine that independently attempts to use transactions.)

Notice that, although a failure handler runs in Non-transactional state when reached because the transaction has failed, it runs in Suspended state for the case discussed in this Programming Note.)
Chapter 5. Transactional Memory Facility [Category: Transactional Memo-
Transactions will fail for the following self-induced causes:

- Termination caused by the execution of `tabort, tabortdc, tabortdc1, tabortwc, tabortwci` or `treclaim` instruction.
- Transaction level overflow, defined as an attempt to perform a storage access in Transactional state which exceeds the capacity for tracking transactional accesses.
- Execution of the following instructions while in the Transactional state: `doze, sleep, nap, rwhinkle, icbi, dcbf, dcbi, dcbst, [h]rfid, rfebb, mtmsr[d], mtse, mtsr, mtstn, msgsnd, msgrnd, msgclr, msgclrp, slbie, slbia, slbmt, slbfee`, and `tlbie[l]`. (These instructions are considered to be disallowed in Transactional state.) The disallowed instruction is not executed; failure handling occurs before it has been executed.

### Programming Note

Note that execution of a Power Saving instruction in Suspended state causes a TM Bad Thing type Program interrupt.

Execution, while in Transactional state, of `mtspr` specifying an SPR that is not part of the checkpointed registers and is not a Transactional Memory SPR. The `mtspr` is not executed; failure handling occurs before it has been executed. (Modification of XERFXCC and CPRX0 are allowed, but the changes will not be rolled back in the event of transaction failure.)

- Conflict caused by a Suspended state store to a block that was previously accessed transactionally. If the store would have been performed by a successful `Store Conditional` instruction, but the `Store Conditional` instruction does not succeed, it is implementation-dependent whether a conflict is detected.
- Conflict caused by a Suspended state `tlbie` that specifies a translation that was previously used transactionally. (This case will be recorded as a translation invalidation conflict because it may be hard to differentiate from a conflict caused by a `tlbie` performed by another thread and because it is highly likely to be a transient failure.)

For each of the following potential causes, the transaction will fail if the absence of failure would compromise transaction semantics; otherwise, whether the transaction fails is undefined.

- Execution of the following instructions while in the Transactional state: `ecwx, ecowx, lbzci, ldci, lhzci, lwzci, stbci, stdci, sthcix, stwci`. The disallowed instruction is not executed; failure handling occurs before it has been executed. (These instructions are considered to be disallowed in Transactional state if they cause transaction failure in Transactional state.) Execution of these instructions in the Suspended state is allowed and does not cause transaction failure.
- Execution of the following instruction in the Transactional state: `wait`. The disallowed instruction is not executed; failure handling occurs before it has been executed. (This instruction is considered to be disallowed in a transaction if it causes transaction failure.)
- Execution of the following instruction in the Suspended state: `wait`. The disallowed instruction is treated as a no-op; failure recording occurs. (This instruction is considered to be disallowed in a transaction if it causes transaction failure.)
- Access of a disallowed type while in the Transactional state: Caching Inhibited, Write Through Required, and Memory Coherence not Required for data access; Caching-Inhibited for instruction fetch. The disallowed access is not performed; failure handling occurs such that the instruction that would cause (or be associated with, for instruction fetch) the disallowed access type appears not to have been executed. Accesses of this type in the Suspended state are allowed and do not cause transaction failure.
- Instruction fetch from a block that was previously written transactionally (reported as a unique cause that includes both self-induced and externally-induced instances)

### Programming Note

Note that `dcbi` with L=3 should never compromise transactional semantics, but it is still permitted to cause transaction failure in Suspended state and it is disallowed in Transactional state.

The instruction (`dcbf, dcbi, or icbi`) is executed in Suspended state on the processor executing the transaction (self-induced conflict)
- the instruction is executed by another processor (externally-induced conflict)
- `dcbst` specifying a block that was previously written transactionally, in either of the following cases.

For each of the following potential causes, the transaction will fail if the absence of failure would compromise transaction semantics; otherwise, whether the transaction fails is undefined.
dcbst is executed by another processor (externally-induced conflict)
Cache eviction of a block that was previously accessed transactionally
Transactions may also fail due to implementation-specific characteristics of the transactional memory mechanism.

__Programming Note__
WARNING: Software should not depend for its correct execution on the behavior (whether or not the relevant transaction fails) of the cases described in the preceding set of bullets. The behavior is likely to vary from design to design. Such a dependence would impact the software's portability without any tangible advantage.

__Programming Note__
Because the atomic nature of a transaction implies an apparent delay of its component accesses until they can be performed in unison, the use of cache control instructions to manage cache residency and/or the performing of storage accesses may have unexpected consequences. Although they may not cause transaction failure directly, their use in a transaction is strongly discouraged.

If an instruction or event does not cause transaction failure, it behaves as defined in the architecture.

The set of failure causes and events are further classified as "precise" and "imprecise" failure causes. All externally induced events are imprecise, and all self-induced events are precise with the exception of the following cases:
- Self-induced conflicts caused by instruction fetch
- Self-induced conflicts caused by footprint overflow
- Self-induced conflicts in Suspended state (because failure handling is deferred in Suspended state).

When failure recording and handling occur (as defined in Section 5.3.2 and 5.3.3) for a precise failure, they will occur precisely according to the sequential execution model, adhering to the following rules:

1. Effects of the failure occur such that all instructions preceding the instruction causing the failure appear to have completed with respect to the executing thread.
2. The instruction causing the failure may appear not to have begun execution (except for causing the failure), or may have completed, depending on the failure cause.
3. Architecturally, no subsequent instruction has begun execution.

Failure handling for imprecise failure types is guaranteed to occur no later than failure handling. Any operation that can cause imprecise failure if performed in-order can also cause imprecise failure if performed out-of-order.

__Programming Note__
Because instruction fetch from a transactionally written block may result in failure, it is recommended that transactionally accessed data and transactionally accessed instructions not be co-located within a single block.

__Programming Note__
The architecture does not detect and cause transaction failure for translation invalidations to transactionally accessed pages or segments, when the translation invalidation is caused by instructions other than `tlbie` (i.e. `slbie`, `sliba`, `tlibel`, `tlbia`). Consequently, software is responsible for terminating transactions in circumstances where such local translation invalidations may affect a local transaction.

### 5.3.2 Recording of Transaction Failure

When transaction failure occurs, information about the cause and circumstances of failure are recorded in SPRs associated with the transactional facility. Failure recording is performed a single time per transaction that fails, controlled by the state of the TEXASR failure summary (FS) bit; when 0, FS indicates that failure recording has not already been performed, and is therefore permissible.

The following RTL function specifies the actions taken during the recording of transaction failure:

```
TMRecordFailure(FailureCause) #FailureCause is 32-bit cause code
if TEXASRFs = 0
  if failure IA known then
    TFIAR ← CIA
    TEXASRy ← 1
  else
    TFIAR ← approximate instruction address
    TEXASRy ← 0
  TEXASR0:31 ← FailureCause
  if MRSRy=0b01 then TEXASRsuspended ← 1
  if environment = Embedded then
    TEXASRPRIVILEGE ← ¬MRSRy || MSRPR
    TFIARPRIVILEGE ← ¬MRSRy || MSRPR
  else
    TEXASRPRIVILEGE ← MRSRy || MSRPR
    TFIARPRIVILEGE ← MRSRy || MSRPR
  TEXASRP ← 1
  TDOOMED ← 1
```

WARNING: Software should not depend for its correct execution on the behavior (whether or not the relevant transaction fails) of the cases described in the preceding set of bullets. The behavior is likely to vary from design to design. Such a dependence would impact the software’s portability without any tangible advantage.

Because instruction fetch from a transactionally written block may result in failure, it is recommended that transactionally accessed data and transactionally accessed instructions not be co-located within a single block.

The architecture does not detect and cause transaction failure for translation invalidations to transactionally accessed pages or segments, when the translation invalidation is caused by instructions other than `tlbie` (i.e. `slbie`, `sliba`, `tlibel`, `tlbia`). Consequently, software is responsible for terminating transactions in circumstances where such local translation invalidations may affect a local transaction.

### 5.3.2 Recording of Transaction Failure

When transaction failure occurs, information about the cause and circumstances of failure are recorded in SPRs associated with the transactional facility. Failure recording is performed a single time per transaction that fails, controlled by the state of the TEXASR failure summary (FS) bit; when 0, FS indicates that failure recording has not already been performed, and is therefore permissible.

The following RTL function specifies the actions taken during the recording of transaction failure:

```
TMRecordFailure(FailureCause) #FailureCause is 32-bit cause code
if TEXASRFs = 0
  if failure IA known then
    TFIAR ← CIA
    TEXASRy ← 1
  else
    TFIAR ← approximate instruction address
    TEXASRy ← 0
  TEXASR0:31 ← FailureCause
  if MRSRy=0b01 then TEXASRsuspended ← 1
  if environment = Embedded then
    TEXASRPRIVILEGE ← ¬MRSRy || MSRPR
    TFIARPRIVILEGE ← ¬MRSRy || MSRPR
  else
    TEXASRPRIVILEGE ← MRSRy || MSRPR
    TFIARPRIVILEGE ← MRSRy || MSRPR
  TEXASRP ← 1
  TDOOMED ← 1
```
When failure recording occurs, the TEXASR and TFIAR SPRs are set indicating the source of failure. When possible, TFIAR is set to the effective address of the instruction that caused the failure, and TEXASR₃₇ is set to 1 indicating that the contents of TFIAR are exact. When the instruction address is not known exactly, an approximate value is placed in TFIAR and TEXASR₃₇ is set to 0. TEXASR bits 0:31 are set indicating the cause of the failure, and the TEXASRₜₚₑₓₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑₚₑₑ₢
TFHAR stores the effective address of the software failure handler used in the event of transaction failure. TFIAR is used to inform software of the exact location of the transaction failure, when possible. TEXASR contains a transaction level indicating the nesting depth of an active transaction, as well as an indicator of the cause of transaction failure and some machine state when the transaction failed. These registers can be written only when in Non-transactional state.

5.4.1 Transaction Failure Handler Address Register (TFHAR)

The Transaction Failure Handler Address Register is a 64-bit SPR that records the effective address of a software failure handler used in the event of transaction failure. Bits 62:63 are reserved.

---

**Programming Note**

The Failure Persistent bit may be viewed as an eighth bit in the failure code in that both fields are supplied by the least significant byte of RA and software may use all eight to differentiate among the cases for which it performs an abort or reclaim. However, software is expected to organize its cases so that bit 7 predicts the persistence of the case.

---

**Warning:** Software must not depend on the value of the Failure Persistent bit for correct execution. The number of retries for a transient failure should be counted, and a limit set after which the program will perform the operation non-transactionally. In the analysis of failures, consideration should be given to the fact that speculative execution can cause unexpected behavior.

---

**Programming Note**

An instruction fetch to storage that is Caching Inhibited, while nominally disallowed, will be reported as Implementation-specific (bit 15). This choice was made because it seems like a relatively unlikely programming error, and there is a significant chance that data from an external conflict (store by another thread) could indirectly cause a wild branch to storage that is Caching Inhibited.

---

**Disallowed**
The instruction, SPR, or access type is not permitted. When set, TFIAR is exact. See Section 5.3.1, “Causes of Transaction Failure”.

---

**Programming Note**

The maximum transaction level was exceeded. When set, TFIAR is exact.

---

**Footprint Overflow**
The tracking limit for transactional storage accesses was exceeded. When set, TFIAR is an approximation.
Self-Induced Conflict
A self-induced conflict occurred in Suspended state, due to one of the following: a store to a block that was previously accessed transactionally; a dcbf, dcbi, or icbi specifying a block that was previously accessed transactionally; a dcbst specifying a block that was previously written transactionally; or a tblie that specifies a translation that was previously used transactionally. When set, TFIAR may be exact.

Non-Transactional Conflict
A conflict occurred with a non-transactional access by another processor. When set, TFIAR is an approximation.

Transaction Conflict
A conflict occurred with another transaction. When set, TFIAR may be exact.

Translation Invalidation Conflict
A conflict occurred with a TLB invalidation. When set, TFIAR is an approximation.

Implementation-specific
An implementation-specific condition caused the transaction to fail. Such conditions are transient and the value in the TFIAR may be exact.

Instruction Fetch Conflict
An instruction fetch (by this or another thread) was performed from a block that was previously written transactionally. Such conditions are transient and the value in the TFIAR may be exact.

Abort
Termination was caused by the execution of a tabort, tabortdc, tabortdci, tabortwc, tabortwci, or treclaim, instruction. When due to tabort, or treclaim, bits in TEXASR0:7 are user-supplied. When set, TFIAR is exact.

Suspended
When set to 1, the failure was recorded in Suspended state. When set to 0, the failure was recorded in Transactional state.

Reserved

Privilege
The thread was in this privilege state when the failure was recorded. For the Embedded environment, this was the value ¬MSRGS II MSRPR when the failure was recorded. For the Server environment, this was the value MSRIV II MSRPR when the failure was recorded.

Failure Summary (FS)
Set to 1 when a failure has been detected and failure recording has been performed.

TFIAR Exact
Set to 1 when the value in the TFIAR is exact. Otherwise the value in the TFIAR is approximate.

ROT
Set to 1 when a ROT is initiated. Set to zero when a non-ROT tbegin, is executed.

Transaction Level (TL)
Transaction level (nesting depth + 1) for the active transaction, if any; otherwise 0 if the most recently executed transaction completed successfully, or the transaction level at which the most recently executed transaction failed if the most recently executed transaction did not complete successfully.

Programming Note
A value of 1 corresponds to an outer transaction. A value greater than 1 corresponds to a nested transaction.

The transaction level in TEXASRtl contains an unsigned integer indicating whether the current transaction is an outer transaction, or is nested, and if nested, its depth. The maximum transaction level supported by a given implementation is of the form 2^t - 1. The value of t corresponding to the smallest maximum is 4; the value of t corresponding to the largest maximum is 12. This value is tied to the “Maximum transaction level” parameter useful for application programmers, as specified in Section 4.1. The high-order 12-t bits of TEXASRtl are treated as reserved.

Transaction failure information is contained in TEXASR0:37. The fields of TEXASR are initialized upon the successful initiation of a transaction from the Non-transactional state, by setting TEXASRtl to 1, indicating an outer transaction, and all other fields to 0.

When transaction failure is recorded, the failure summary bit TEXASRFS is set to 1, indicating that failure has been detected for the active transaction and that failure recording has been performed. TEXASR0:31 are set indicating the source of the failure. Exactly one of bits 8 through 31 will be set indicating the instruction or event that caused failure. In the event of failure due to
the execution of a `tabort`, `tabortdc`, `tabortdci`, `tabortwc`, `tabortwci`, or `treclaim` instruction, `TEXASR31` is set to 1, and, for `tabort` and `treclaim`, a software defined failure code is copied from a register operand to `TEXASR0:7`. `TEXASRSuspended` indicates whether the transaction was in the Suspended state at the time that failure occurred. The inverse of the value of MSRGS and the value of MSRPR for the Embedded environment or the values of MSRHV and MSRPR for the Server environment at the time that failure occurs are copied to `TEXASR34` and `TEXASR35`, respectively. In some circumstances, the failure causing instruction address in TFIAR may not be exact. In such circumstances, `TEXASR37` is set to 0 indicating that the contents of TFIAR are not exact; otherwise `TEXASR37` is set to 1.

5.4.3 Transaction Failure Instruction Address Register (TFIAR)

The Transaction Failure Instruction Address Register is a 64-bit SPR that is set to the exact effective address of the instruction causing the failure, when possible. Bits 62:63 contain the privilege state when the instruction causing the failure, when possible. For the Embedded environment, this was the value `¬MSRGS` || `MSRPR` when the failure was recorded. For the Server environment, this was the value `MSRHV` || `MSRPR` when the failure was recorded. For the Server environment, this was the value `MSRHV` || `MSRPR` when the failure was recorded.

<table>

<td>0</td>
<td></td>
</tr>
</tbody>
</table>

Figure 8. Transaction Failure Instruction Address Register (TFIAR)

In certain cases, the exact address may not be available, and therefore TFIAR will be an approximation. An approximate value will point to an instruction near the instruction that was executing at the time of the failure. TFIAR accuracy is recorded in an Exact bit residing in `TEXASR37`.

Programming Note

The transaction level contained in `TEXASR_TL` should be interpreted by software as follows:

When in the Transactional or Suspended state, this field contains an unsigned integer representing the transaction level of the active transaction, with 1 indicating an outer transaction, and a number greater than 1 indicating a nested transaction. The nesting depth of the active transaction is `TEXASR_TL` – 1.

When in the Non-transactional state, `TEXASR_TL` contains 0 if the last transaction committed successfully, otherwise it contains the transaction level at which the most recent transaction failed.

Programming Note

The Privilege bits in `TEXASR` represent the state of the machine at the point when failure occurs. This information may be used by problem-state software to determine whether an unexpected hypervisor or operating system interaction was responsible for transaction failure. This information may be useful to operating systems or hypervisors when restoring register state for failure handling after the transactional facility was reclaimed, to determine which of the operating system or the hypervisor has retained the pre-transactional version of the checkpointed registers.

5.4.3 Transaction Failure Instruction Address Register (TFIAR)

The Transaction Failure Instruction Address Register is a 64-bit SPR that is set to the exact effective address of the instruction causing the failure, when possible. Bits 62:63 contain the privilege state when the instruction causing the failure, when possible.
5.5 Transactional Facility Instructions

Similar to the Floating-Point Status and Control Register instructions, modifications of transaction state caused by the execution of Transactional Memory instructions or by failure handling synchronize the effects of exception-causing floating-point instructions executed by a given processor. Executing a Transactional Memory instruction, or invocation of the failure handler, ensures that all floating-point instructions previously initiated by the given processor have completed before the transaction state is modified, and that no subsequent floating-point instructions are initiated by the given processor until the transaction state has been modified. In particular:

- All exceptions that will be caused by the previously initiated instructions are recorded in the FPSCR before the transaction state is modified.
- All invocations of the system floating-point enabled exception error handler that will be caused by the previously initiated instructions have occurred before the transaction state is modified.
- No subsequent floating-point instruction that alters the settings of any FPSCR bits is initiated until the transaction state has been modified.

(Floating-point Storage Access instructions are not affected.)

        TEXASRROTr ← 0
        (Floating-point Storage Access instructions are not affected.)

The tbegin. instruction initiates execution of a transaction, either an outer transaction or a nested transaction, as described below.

An outer transaction is initiated when tbegin. is executed in the Non-transactional state. If R=0 and the transaction is successful, a memory barrier is inserted equivalent to that produced by a sync instruction with E=0b1111. (See Section 4.4.3.) TEXASR and TFHAR are initialized, and the TDOOMED bit is set to 0. A nested transaction is initiated when tbegin. is executed in the Transactional state unless the transaction level is already at its maximum value, in which case failure recording is performed with a failure cause of 0x014000000 and failure handling is performed. When initiating a nested transaction, the transaction level held in TEXASR is incremented by 1, and if TEXASR ROT =1 but R=0, and the transaction succeeds, a memory barrier is inserted equivalent to that produced by a sync instruction with E=0b1111 and TEXASR ROT is turned off. The effects of a nested transaction will not be visible until the outer transaction commits, and in the event of failure, the checkpointed registers are reverted to the pre-transactional values of the outer transaction. Initiation of a transaction is unsuccessful when in the Suspended state.

When successfully initiated, transactional execution continues until the transaction is terminated using a tend., tabort., tabortdc., tabortwci., tabortwc., or treclaim. instruction, suspended using a tsr instruction, or failure occurs. Upon transaction failure while in the Transactional state, transaction failure recording and failure handling are performed as defined in Section 5.3. Upon transaction failure while in the Suspended state, failure recording is performed as defined in Section 5.3.2, but failure handling is usually deferred.
CR0 is set as follows.

<table>
<thead>
<tr>
<th>CR0</th>

Other than the setting of CR0, tbegin. in the Suspended state is treated as a no-op.

The use of the A field is implementation specific.

Special Registers Altered
CR0 TEXASR TFHAR TS

Programming Note
When a transaction is successfully initiated, and failure subsequently occurs, control flow will be redirected to the instruction following the tbegin. instruction. When failure handling occurs, as described in Section 5.3.3, CR0 is set to 0b101 0. Consequently, instructions following tbegin. should also expect this value as an indication of transaction failure. Most applications will follow tbegin. with a conditional branch predicates on CR02; code at this target is responsible for handling the transaction failure.

The A=0 variant of tend. supports nested transactions, in which the transaction is committed only if the execution of tend. completes an outer transaction. Execution of this variant by a nested transaction (TEXASR_TL > 1) causes TEXASR_TL to be decremented by 1. The A=1 variant of tend. unconditionally completes the current outer transaction and all nested transactions.

When the tend. instruction completes an outer transaction, transaction commit is predicated on the TDOOMED bit. If TDOOMED is 1, failure handling occurs as defined in Section 5.3.3. If TDOOMED is 0, the transaction is committed, and TEXASR_TL is set to 0. In both cases, the transaction state is set to Non-transactional.

When the tend. instruction commits a transaction, it atomically commits its writes to storage. If TEXASR_ROT=0, the integrated cumulative memory barrier is inserted prior to the creation of the aggregate store, and a memory barrier is inserted equivalent to that produced by a sync instruction with E=0b1111 after the aggregate store. (See Section 4.4.3.) If the transaction has failed prior to the execution of tend., no storage updates are performed and no memory barrier is inserted. In either case (success or failure), all resources associated with the transaction are discarded.

If the transaction succeeds, Condition Register field 0 is set to 0 || MSR_TS || 0. If the transaction fails, CR0 is set to 0b101 0.
Other than the setting of CR0, `tend`, in Non-transactional state is treated as a no-op. If an attempt is made to execute `tend` in Suspended state, a TM Bad Thing type Program interrupt occurs.

**tabortdc.**  

| TO | RA | RB | 814 | 1 |

\[
\text{tabortdc.} \leftarrow \text{TO,RA,RB}
\]
The `tabortdc` instruction sets condition register field 0 to 0 || MSR_T8 || 0. The contents of register RA are compared with the sign-extended value of the SI field. If any bit in the TO field is set to 1 and its corresponding condition is met by the result of the comparison, and the transaction state is Transactional or Suspended, then the `tabortdc` instruction causes transaction failure, resulting in the following:

Failure recording is performed as defined in Section 5.3.2, using the failure cause 0x00000001.

If the transaction state is Transactional, failure handling is performed as defined in Section 5.3.3 (this includes discarding the transactional footprint).

If the transaction state is Suspended, the transactional footprint is discarded (if not already discarded for a pending failure), but failure handling is deferred.

Other than the setting of CR0, execution of `tabortdc` in the Non-transactional state is treated as a no-op.

### Special Registers Altered

- CR0: MSR_T8, TFIAR, TS

### Transaction Suspend or Resume X-form

The `tsr` instruction suspends or resumes a transaction based on the value of the L field in the special register TFIAR.

The `tsr` instruction sets condition register field 0 to 0 || MSR_T8 || 0. The contents of register RA are compared with the sign-extended value of the SI field. If any bit in the TO field is set to 1 and its corresponding condition is met by the result of the comparison, and the transaction state is Transactional or Suspended, then the `tabortdc` instruction causes transaction failure, resulting in the following:

Failure recording is performed as defined in Section 5.3.2, using the failure cause 0x00000001.

If the transaction state is Transactional, failure handling is performed as defined in Section 5.3.3 (this includes discarding the transactional footprint).

If the transaction state is Suspended, the transactional footprint is discarded (if not already discarded for a pending failure), but failure handling is deferred.

Other than the setting of CR0, execution of `tabortdc` in the Non-transactional state is treated as a no-op.
The `tsr` instruction sets condition register field 0 to 0 || MSR₇₈ || 0. Based on the value of the L field, two variants of `tsr` are used to change the transaction state.

If L = 0, and the transaction state is Transactional, the transaction state is set to Suspended.

If L = 1, and the transaction state is Suspended, the transaction state is set to Transactional.

Other than the setting of CR0, the execution of `tsr` in the Non-transactional state is treated as a no-op.

### Special Registers Altered

CR0 TS

---

### Programming Note

When resuming a transaction that has encountered failure while in the Suspended state, failure handling is performed after the execution of `resume` and no later than the next failure synchronizing event.

### Extended Mnemonics

Extended mnemonics for Transaction Suspend or Resume.

<table>
<thead>

</tbody>
</table>

### Transaction Check X-form

<table>
<thead>
<tr>
<th>tcheck</th>
<th>BF</th>
</tr>
</thead>
<tbody>
<tr>
<td>31 BF // // // 718 /</td>
<td></td>
</tr>
</tbody>
</table>

If MSR₇₈ = 0b10 | MSR₇₈ = 0b01 then #Transaction
| for Suspended |
| for each load caused by an instruction following the outer `tbegin` and preceding this `tcheck` |
| if (Load instruction was executed in T state with TEXASR₉₀=0 or accessing a location previously stored transactionally) |
| (Load instruction was executed in S state with TEXASR₉₀=0 and accessed a location previously accessed transactionally) |
| (Load instruction was executed in S state with TEXASR₉₀=0 and accessing a location previously stored transactionally) |
| then wait until load has been performed with respect to all processors and mechanisms |
| CR field BF ← TDOOMED || MSR₇₈ || 0 |

If the transaction state is Transactional or Suspended, the `tcheck` instruction ensures that all loads that are caused by instructions that follow the outer `tbegin` instruction and precede the `tcheck` instruction and satisfy one of the following properties, have been performed with respect to all processors and mechanisms.

- The load is caused by an instruction that was executed in Transactional state, either while TEXASR₉₀=0 or accessing a location previously stored transactionally.
- The load is caused by an instruction that was executed in Suspended state while TEXASR₉₀=0 and accesses a location that was accessed transactionally.
- The load is caused by an instruction that was executed in Suspended state while TEXASR₉₀=1 and accesses a location that was stored transactionally.

The `tcheck` instruction then copies the TDOOMED bit into bit 0 of CR field BF, copies MSR₇₈ to bits 1:2 of CR field BF, and sets bit 3 of CR field BF to 0.

Other than the setting of CR field BF, execution of `tcheck` in the Non-transactional state is treated as a no-op.

### Special Registers Altered

CR field BF
One use of the `tcheck` instruction in Suspended state is to determine whether preceding loads from transactionally modified locations have returned the data the transaction stored. (If the transaction has failed, some of the loads may have returned a more recent value that was stored by a conflicting store, or may have returned the pre-transaction contents of the location.). It is important to use `tcheck` between any Suspended state loads that might access transactionally modified locations and subsequent computation using the Suspended-state-loaded data. Otherwise, corrupt data could cause problems such as wild branches or infinite loops.

Another use of `tcheck` in Suspended state is to determine whether the contents of storage, as seen in Suspended state, are consistent with the transaction succeeding -- e.g., whether no location that has been accessed transactionally (stored transactionally, for ROTs), and has been seen in Suspended state, has been subject to a conflict thus far. (A location is seen in Suspended state either by being loaded in Suspended state or by being loaded in Transactional state and the value (or a value derived therefrom) passed, in a register, into Suspended state.)

A use of `tcheck` in Transactional state is to determine whether the transaction still has the potential to succeed.

Note that `tcheck` provides an instantaneous check on the integrity of a subset of the accesses performed within a transaction. `tcheck` is not a failure synchronizing mechanism. Even if no accesses follow the `tcheck`, there may still be latent failures that haven’t been recorded, for example caused by accesses that `tcheck` does not wait for, by external conflicts that will happen in the future, or simply by time of flight to the failure detection mechanism for operations that have already been performed.

The `tcheck` instruction can return 1 in bit 0 of CR field BF before the failure has been recorded in TEXASR and TFIAR.

The `tcheck` instruction may cause pipeline synchronization. As a result, programs that use `tcheck` excessively may perform poorly.
Chapter 6.  Time Base

6.1 Time Base Overview

The time base facilities include a Time Base and an Alternate Time Base which is category: Alternate Time Base. The Alternate Time Base is analogous to the Time Base except that it may count at a different frequency and is not writable.

6.2 Time Base

The Time Base (TB) is a 64-bit register (see Figure 9) containing a 64-bit unsigned integer that is incremented periodically as described below.

The suggested frequency at which the time base increments is 512 MHz, however, variation from this rate is allowed provided the following requirements are met.

- The contents of the Time Base differ by no more than +/- four counts from what they would be if they incremented at the required frequency.
- Bit 63 of the Time Base is set to 1 between 30% and 70% of the time over any time interval of at least 16 counts.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock. The Time Base update frequency is not required to be constant. What is required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

6.2.1 Time Base Instructions

**Move From Time Base**  
XFX-form

```
mtfb  RT,TBR
```

[Category: Phased-Out]

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TBU</td>
<td>Upper 32 bits of Time Base</td>
</tr>
<tr>
<td>TBL</td>
<td>Lower 32 bits of Time Base</td>
</tr>
</tbody>
</table>

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from $2^{64}-1$ to $0$). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.

Programming Note

If the operating system initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

This instruction behaves as if it were an `mfspr` instruction; see the `mfspr` instruction description in Section 3.3.16 of Book I.

Special Registers Altered:

None
Extended Mnemonics:

Extended mnemonics for Move From Time Base:

<table>
<thead>

</tr>
<tr>
<td>mftbu Rx</td>
<td>mftb Rx,269</td>
</tr>
<tr>
<td></td>
<td>mfspr Rx,269</td>
</tr>
</tbody>
</table>

**Programming Note**

New programs should use `mfspr` instead of `mftb` to access the Time Base.

**Programming Note**

`mftb` serves as both a basic and an extended mnemonic. The Assembler will recognize an `mftb` mnemonic with two operands as the basic form, and an `mftb` mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).

**Programming Note**

The `mfspr` instruction can be used to read the Time Base on all processors that comply with Version 2.01 of the architecture or any subsequent version.

It is believed that the `mfspr` instruction can be used to read the Time Base on most processors that comply with versions of the architecture that precede Version 2.01. Processors for which `mfspr` cannot be used to read the Time Base include the following.

- 601
- POWER3

(601 implements neither the Time Base nor `mftb`, but depends on software using `mftb` to read the Time Base, so that the attempt causes the Illegal Instruction error handler to be invoked and thereby permits the operating system to emulate the Time Base.)
Since the update frequency of the Time Base is implementation-dependent, the algorithm for converting the current value in the Time Base to time of day is also implementation-dependent.

As an example, assume that the Time Base increments at the constant rate of 512 MHz. (Note, however, that programs should allow for the possibility that some implementations may not increment the least-significant 4 bits of the Time Base at a constant rate.) What is wanted is the pair of 32-bit values comprising a POSIX standard clock: the number of whole seconds that have passed since 00:00:00 January 1, 1970, UTC, and the remaining fraction of a second expressed as a number of nanoseconds.

Assume that:

- The value 0 in the Time Base represents the start time of the POSIX clock (if this is not true, a simple 64-bit subtraction will make it so).
- The integer constant `ticks_per_sec` contains the value 512,000,000, which is the number of times the Time Base is updated each second.
- The integer constant `ns_adj` contains the value \( \frac{1,000,000,000}{512,000,000} \times 2^{32} / 2 = 4194304000 \)
  which is the number of nanoseconds per tick of the Time Base, multiplied by \( 2^{32} \) for use in `mulhwu` (see below), and then divided by 2 in order to fit, as an unsigned integer, into 32 bits.

When the processor is in 64-bit mode, The POSIX clock can be computed with an instruction sequence such as this:

```assembly
mulld Rz,Rz,Rx  # Rz = quotient * divisor
sub Rz,Ry,Rz    # Rz = excess ticks
lwz  Rx,ns_adj
slwi Rz,Rz,1    # Rz = 2 * excess ticks
mulhwu Rz,Rz,Rx # mul by (ns/tick)/2 * 2^{32}
stw  Rz,posix_ns# product[0:31] = excess ns
```

For the Embedded environment when the processor is in 32-bit mode, it is not possible to read the Time Base using a single instruction. Instead, two instructions must be used, one of which reads TBL and the other of which reads TBU. Because of the possibility of a carry from TBL to TBU occurring between the two reads, a sequence such as the following must be used to read the Time Base.

```assembly
loop:
mfspr Rx,TBU  # load from TBU
mfspr Ry,TB  # load from TB
mfspr Rz,TBU  # load from TBU
cmp cr0,0,Rx,Rz# check if ‘old‘=‘new’
bne loop  #branch if carry occurred
```

### Non-constant update frequency

In a system in which the update frequency of the Time Base may change over time, it is not possible to convert an isolated Time Base value into time of day. Instead, a Time Base value has meaning only with respect to the current update frequency and the time of day that the update frequency was last changed. Each time the update frequency changes, either the system software is notified of the change via an interrupt (see Book III), or the change was instigated by the system software itself. At each such change, the system software must compute the current time of day using the old update frequency, compute a new value of `ticks_per_sec` for the new frequency, and save the time of day, Time Base value, and tick rate. Subsequent calls to compute Time of Day use the current Time Base Value and the saved value.

---

6.3 Alternate Time Base [Category: Alternate Time Base]

The Alternate Time Base (ATB) is a 64-bit register (see Figure 9) containing a 64-bit unsigned integer that is incremented periodically. The frequency at which the integer is updated is implementation-dependent.

The ATBL register is an aliased name for the ATB.

The Alternate Time Base increments until its value becomes 0xFFFF_FFFF_FFFF_FFFF \((2^{64} - 1)\). At the next increment, its value becomes 0x0000_0000_0000_0000. There is no explicit indication (such as an interrupt; see Book III) that this has occurred.

The Alternate Time Base is accessible in both user and supervisor mode. The counter can be read by executing a `mfspr` instruction specifying the ATB (or ATBL) register, but cannot be written. A second SPR register ATBU, is defined that accesses only the upper 32 bits of the counter. Thus the upper 32 bits of the counter may be read into a register by reading the ATBU register.

The effect of entering a power-savings mode or of processor frequency changes on counting in the Alternate Time Base is implementation-dependent.
Chapter 7. Event-Based Branch Facility [Category: Server]

7.1 Event-Based Branch Overview

The Event-Based Branch facility allows application programs to enable hardware to change the effective address of the next instruction to be executed when certain events occur to an effective address specified by the program.

The operation of the Event-Based Branch facility is summarized as follows:

- The Event-Based Branch facility is available only when the system program has made it available. See Section 9.5 of Book III-S for additional information.

- When the Event-Based Branch facility is available, event-based branches are caused by event-based exceptions. Event-based exceptions can be enabled to occur by setting bits in the Event Control field of the BESCR.

- When an event-based exception occurs, the bit in the BESCR control field corresponding to the event-based exception is set to 0 and the bit in the Event Status field in the BESCR corresponding to the event-based exception is set to 1.

- If the global enable bit in the BESCR is set to 1 when any of the bits in the status field are set to 1 (i.e. when an event-based exception exists), an event-based branch occurs.

- The event-based branch causes the global enable bit to be set to 0, causes instruction fetch and execution to continue at the effective address contained in the EBBHR, and causes the TS field of the BESCR to indicate the transactional state of the processor when the event-based branch occurred. If the processor was in transactional state when the event-based branch occurred, it is put into suspended state. The EBBRR is set to the effective address of the instruction that would have attempted to execute next if no event-based branch had occurred.

- The event-based branch handler performs the necessary processing in response to the event, and then executes an `rfebb` instruction in order to resume execution at the instruction that would have been executed next when the event-based branch occurred. The `rfebb` instruction also restores the processor to the transactional state indicated by BESCRTS.

Additional information about the Event-Based Branch facility is given in Section 3.4 of Book III-S.

**Programming Note**

Since system software controls the availability of the Event-Based Branch facility (see Section 9.5 of Book III-S), an interface must be provided that enables applications to request access to the facility and determine when it is available.

**Programming Note**

In order to initialize the Event-Based Branch facility for Performance Monitor event-based exceptions, software performs the following operations.

- Software requests control of the Event-Based Branch facility from the system program.

- Software requests the System Program to initialize the Performance Monitor as desired.

- Software sets the EBBHR to the effective address of the event-based branch handler.

- Software enables Performance Monitor event-based exceptions in the BESCR Control Field by setting BESCRPME to 1. BESCRPME0 should also be set to 0.

- Software sets the GE bit in the BESCR to enable event-based branches.
7.2 Event-Based Branch Registers

7.2.1 Branch Event Status and Control Register

The Branch Event Status and Control Register (BESCR) is a 64-bit register that contains control and status information about the Event-Based Branch facility.

The entire BESCR can be read or written using SPR 806. Individual bits of the BESCR can be set or reset using two sets of additional SPR numbers.

- When mtspr indicates SPR 800 (Branch Event Status and Control Set, or BESCRS), the bits in BESCR which correspond to “1” bits in the source register are set to 1; all other bits in the BESCR are unaffected. SPR 801 (BESCRSU) provides the same capability to each of the upper 32 bits of the BESCR.

- When mtspr indicates SPR 802 (Branch Event Status and Control Reset, or BESCCR), the bits in BESCR which correspond to “1” bits in the source register are set to 0; all other bits in the BESCR are unaffected. SPR 803 (BESCRRU) provides the same capability to each of the upper 32 bits of the BESCR.

When mtspr indicates any of the above SPR numbers, the current value of the register is returned.

Programming Note

Event-based branch handlers typically reset event status bits upon entry, and enable event enable bits after processing an event. Execution of rfebb then re-enables the GE bit so that additional event-based branches can occur.

<table>
<thead>

63  Performance Monitor Event-Based Exception Occurred (PMEO)
0  Performance Monitor event-based exception has not occurred since the last time software set this bit to 0.
1  A Performance Monitor event-based exception has occurred since the last time software set this bit to 0.

This bit is set to 1 by the hardware when a Performance Monitor event-based exception occurs. This bit can be set to 0 only by the mtspri instruction.

See Chapter 9 of Book III-S for information about performance monitor event-based exceptions and about the effects of this bit on the Performance Monitor.

---

**Programming Note**

Software should set this bit to 0 after handling an event-based branch due to a Performance Monitor event-based exception.

---

7.2.2 Event-Based Branch Handler Register

The Event-Based Branch Handler Register (EBBHR) is a 64-bit register register that contains the 62 most significant bits of the effective address of the instruction that is executed next after an event-based branch occurs. Bits 62:32 must be available to be read and written by software.

<table>
<thead>
<tr>
<th>Effective Address</th>
</tr>
</thead>

7.2.3 Event-Based Branch Return Register

The Event-Based Branch Return Register (EBBRR) is a 64-bit register that contains the 62 most significant bits of an instruction effective address as specified below.

<table>
<thead>
<tr>
<th>Effective Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>62 63</td>
</tr>
</tbody>
</table>

---

**Figure 14. Event-Based Branch Return Register (EBBRR)**

When an event-based branch occurs, bits 0:61 of the EBBRR are set to the effective address of the instruction that the processor would have attempted to execute next if no event-based branch had occurred. Bits 62:63 are reserved.
7.3 Event-Based Branch Instructions

*Return from Event-Based Branch*  
**XL-form**

```
rfebb S
```

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th>O</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>6</td>
<td>11</td>
<td>16</td>
<td>20</td>
<td>21</td>
</tr>
</tbody>
</table>

BESCRGE $\leftarrow$ S  
MSR$_{TS}$ $\leftarrow$ BESCR$_{FS}$  
NIA $\leftarrow$ \texttt{EBBRR0:61} || 0b00

BESCRGE is set to S. The processor is placed in the transactional state indicated by BESCR$_{TS}$.

If there are no pending event-based exceptions, then the next instruction is fetched from the address EBBRR$_{0:61}$ || 0b00 (when MSR$_{SF}=1$) or EBBRR$_{32:61}$ || 0b00 (when MSR$_{SF}=0$). If one or more pending event-based exceptions exist, an event-based branch is generated; in this case the value placed into EBBRR by the Event-Based Branch facility is the address of the instruction that would have been executed next had the event-based branch not occurred.

See Section 3.4 of Book III-S for additional information about this instruction.

**Special Registers Altered:**

BESCR  
MSR (See Book III-S)

**Extended Mnemonics:**

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>rfebb</td>
<td>rfebb 1</td>
</tr>
</tbody>
</table>

**Programming Note**

*rfebb* serves as both a basic and an extended mnemonic. The Assembler will recognize an *rfebb* mnemonic with one operand as the basic form, and an *rfebb* mnemonic with no operand as the extended form. In the extended form, the S operand is omitted and assumed to be 1.

If the BESCR$_{TS}$ has been modified by software after an event-based branch occurs, an illegal transaction state transition may occur. See Chapter 3.2.2 of Book III-S.

---

When an event-based branch occurs, the event-based branch handler executes the following sequence of operations. This sequence of operations assumes that the handler has access to a stack or other area in memory in which state information from the main program can be stored. Note also that in this example, the handler entry point is labeled “E,” r1 is used as a scratch register, and only Performance Monitor events are enabled.

```
E:Save state  // This is the entry pt
mfspr r1, BESCR // Check event status
Process event
r1 $\leftarrow$ 0x0000 0000 0000 0001
mtspr BESCR, r1
    //Reset PMAO event status bit
    //Note: The PMAO bit of MMCR0 must also
    //      be reset. See Book III-S.
     r1 $\leftarrow$ 0x0000 0001 0000 0000
mtspr BESCR$_{S}$, r1
    //Enable PME bit
    //Note: The PME bit of MMCR0 must also
    //      be enabled. See Book III-S.
Restore state
rfebb 1       // return & global enable
```
Chapter 8. Decorated Storage Facility [Category: Decorated Storage]

The Decorated Storage facility provides Load, Store, and Notify operations to storage that have additional semantics other than the reading and writing of data values to the addressed storage locations. A decoration is specified that provides semantic information about how the operation is to be performed. A decorated device is a device that implements an address range of storage, and applies decorations to operations performed on the address range of storage.

A Decorated Storage instruction specifies the following attributes:
- The type of access, which is either a Decorated Load, Decorated Store, or a Decorated Notify.
- The EA in register RB, to which the operation is to be performed.
- The decoration in register RA, which further defines what operation should be performed by the decorated device.
- The data itself, either data provided by the processor to the decorated device (in the case of a Decorated Load), or the data provided by the decorated device to be consumed by the processor (in the case of a Decorated Store). Decorated Notify operations do not contain data.

The semantics of any Decorated Storage operation that is Caching Inhibited are defined by the decorated device depending on whether it is a Decorated Load, Decorated Store, or Decorated Notify, and the value supplied as a decoration. Such semantics may differ from decorated device to decorated device similar to how devices other than well-behaved memory may treat Load and Store operations. The semantics of any operation associated with a Decorated Storage operation that is not Caching Inhibited are the same as an analogous Load or Store instruction of the same data size.

The results of a Decorated Storage operation that is Caching Inhibited to a device that does not support decorations is boundedly undefined. The results of a Load or Store operation that is Caching Inhibited to a decorated device that requires a decoration is boundedly undefined.

For Decorated Load operations, a Load operation with the specified decoration is performed to the EA and the data provided by the decorated device is placed in the target register.

For Decorated Store operations, a Store operation using the data specified in the source register with the specified decoration is performed to the EA.

Decorated Load instructions are treated as Load instructions for address translation, access control, debug events, storage attributes, alignment, and memory access ordering. Decorated Store instructions are treated as Store instructions for address translation, access control, debug events, storage attributes, alignment, and memory access ordering. A Decorated Notify instruction is treated as a zero byte Store for address translation, access control, debug events, storage attributes, alignment, and memory access ordering.

**Programming Note**
Software should be acutely aware of how transactions to a decorated device that implements Decorated Storage will occur. Not only does this imply knowing the particular decorated device’s semantics, but also ensuring that the transactions are appropriately issued by the processor. This includes alignment, speculative accesses, and ordering. In general, Caching Inhibited accesses are required to be Guarded and properly aligned.
8.1 Decorated Load Instructions

**Load Byte with Decoration Indexed X-form**

```plaintext
lbdx RT,RA,RB
```

EA \(\leftarrow (RB)\)

RT \(\leftarrow 560 \ || \ \text{MEM\_DECORATED}(EA,1,(RA))\)

Let the effective address (EA) be the contents of RB. The byte in storage addressed by EA is loaded using the decoration supplied by (RA) into RT\textsubscript{56:63}. RT\textsubscript{0:55} are set to 0.

**Special Registers Altered:**
None

**Load Halfword with Decoration Indexed X-form**

```plaintext
lhdx RT,RA,RB
```

EA \(\leftarrow (RB)\)

RT \(\leftarrow 480 \ || \ \text{MEM\_DECORATED}(EA,2,(RA))\)

Let the effective address (EA) be the contents of RB. The halfword in storage addressed by EA is loaded using the decoration supplied by (RA) into RT\textsubscript{48:63}. RT\textsubscript{0:47} are set to 0.

**Special Registers Altered:**
None

**Load Word with Decoration Indexed X-form**

```plaintext
lwdx RT,RA,RB
```

EA \(\leftarrow (RB)\)

RT \(\leftarrow 320 \ || \ \text{MEM\_DECORATED}(EA,4,(RA))\)

Let the effective address (EA) be the contents of RB. The word in storage addressed by EA is loaded using the decoration supplied by (RA) into RT\textsubscript{32:63}. RT\textsubscript{0:31} are set to 0.

**Special Registers Altered:**
None

**Load Doubleword with Decoration Indexed X-form**

```plaintext
lddx RT,RA,RB [Co-requisite category: 64-Bit]
```

EA \(\leftarrow (RB)\)

RT \(\leftarrow \text{MEM\_DECORATED}(EA,8,(RA))\)

Let the effective address (EA) be the contents of RB. The doubleword in storage addressed by EA is loaded using the decoration supplied by (RA) into RT.

**Special Registers Altered:**
None

**Load Floating Doubleword with Decoration Indexed X-form**

```plaintext
lfddx FRT,RA,RB [Co-requisite category: FP]
```

EA \(\leftarrow (RB)\)

FRT \(\leftarrow \text{MEM\_DECORATED}(EA,8,(RA))\)

Let the effective address (EA) be the contents of RB. The doubleword in storage addressed by EA is loaded using the decoration supplied by (RA) into FRT.

**Special Registers Altered:**

EA \(\rightarrow\) (RB)
MEM_NOTIFY(EA, (RA))

Let the effective address (EA) be the contents of RB. The decoration supplied by (RA) is sent to the address in storage specified by EA.

Special Registers Altered:

None
Chapter 9. External Control [Category: External Control]

The External Control category of facilities and instructions permits a program to communicate with a special-purpose device. Two instructions are provided, both of which must be implemented if the facility is provided.

- **External Control In Word Indexed** (*eciwx*), which does the following:
  - Computes an effective address (EA) like most X-form instructions
  - Validates the EA as would be done for a load from that address
  - Translates the EA to a real address
  - Transmits the real address to the device
  - Accepts a word of data from the device and places it into a General Purpose Register

- **External Control Out Word Indexed** (*ecowx*), which does the following:
  - Computes an effective address (EA) like most X-form instructions
  - Validates the EA as would be done for a store to that address
  - Translates the EA to a real address
  - Transmits the real address and a word of data from a General Purpose Register to the device

Permission to execute these instructions and identification of the target device are controlled by two fields, called the E bit and the RID field respectively. If attempt is made to execute either of these instructions when E=0 the system data storage error handler is invoked. The location of these fields is described in Book III.

The storage access caused by *eciwx* and *ecowx* is performed as though the specified storage location is Caching Inhibited and Guarded, and is neither Write Through Required nor Memory Coherence Required.

Interpretation of the real address transmitted by *eciwx* and *ecowx* and of the 32-bit value transmitted by *ecowx* is up to the target device, and is not specified by the Power ISA. See the System Architecture documentation for a given Power ISA system for details on how the External Control facility can be used with devices on that system.

**Example**

An example of a device designed to be used with the External Control facility might be a graphics adapter. The *ecowx* instruction might be used to send the device the translated real address of a buffer containing graphics data, and the word transmitted from the General Purpose Register might be control information that tells the adapter what operation to perform on the data in the buffer. The *eciwx* instruction might be used to load status information from the adapter.

A device designed to be used with the External Control facility may also recognize events that indicate that the address translation being used by the processor has changed. In this case the operating system need not “pin” the area of storage identified by an *eciwx* or *ecowx* instruction (i.e., need not protect it from being paged out).
9.1 External Access Instructions

In the instruction descriptions the statements “this instruction is treated as a Load” and “this instruction is treated as a Store” have the same meanings as for the Cache Management instructions; see Section 4.3.

External Control In Word Indexed X-form
eciwx RT,RA,RB

<table>
<thead>
<tr>
<th></th>
<th>RT</th>
<th>RA</th>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td>6</td>
<td>11</td>
<td>16</td>
</tr>
</tbody>
</table>

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
raddr ← address translation of EA
send load word request for raddr to
device identified by RID
RT ← 320 || word from device

Let the effective address (EA) be the sum (RA|0)+(RB).

A load word request for the real address corresponding to EA is sent to the device identified by RID, bypassing the cache. The word returned by the device is placed into RT32:63. RT0:31 are set to 0.

The E bit must be 1. If it is not, the data storage error handler is invoked.

EA must be a multiple of 4. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

This instruction is treated as a Load.

See Book III-S for additional information about this instruction.

Special Registers Altered:
None

Programming Note

The eieio<SS> or mbar<E> instruction can be used to ensure that the storage accesses caused by eciwx and ecowx are performed in program order with respect to other Caching Inhibited and Guarded storage accesses.

External Control Out Word Indexed X-form
ecowx RS,RA,RB

<table>
<thead>
<tr>
<th></th>
<th>RS</th>
<th>RA</th>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td>6</td>
<td>11</td>
<td>16</td>
</tr>
</tbody>
</table>

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
raddr ← address translation of EA
send store word request for raddr to
device identified by RID
send (RS)32:63 to device

Let the effective address (EA) be the sum (RA|0)+(RB).

A store word request for the real address corresponding to EA and the contents of RS32:63 are sent to the device identified by RID, bypassing the cache.

The E bit must be 1. If it is not, the data storage error handler is invoked.

EA must be a multiple of 4. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

This instruction is treated as a Store, except that its storage access is not performed in program order with respect to accesses to other Caching Inhibited and Guarded storage locations unless software explicitly imposes that order.

See Book III-S for additional information about this instruction.

Special Registers Altered:
None
Appendix A. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided for certain instructions. This appendix defines extended mnemonics and symbols related to instructions defined in Book II. Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

A.1 Data Cache Block Flush Mnemonics

The L field in the Data Cache Block Flush instruction controls the scope of the flush function performed by the instruction. Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

Note: dcbf serves as both a basic and an extended mnemonic. The Assembler will recognize a dcbf mnemonic with three operands as the basic form, and a dcbf mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.

\[
\begin{align*}
dcbf RA,RB & \quad (\text{equivalent to: } dcbf RA,RB,0) \\
dcbfl RA,RB & \quad (\text{equivalent to: } dcbf RA,RB,1)
\end{align*}
\]

A.2 Load and Reserve Mnemonics

The EH field in the Load and Reserve instructions provides a hint regarding the type of algorithm implemented by the instruction sequence being executed. Extended mnemonics are provided that allow the EH value to be omitted and assumed to be 0b0.

Note: lbarx, lbarx, lwarx, ldarx, and lqarx serve as both basic and extended mnemonics. The Assembler will recognize these mnemonics with four operands as the basic form, and these mnemonics with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

\[
\begin{align*}
lbarx RT,RA,RB & \quad (\text{equivalent to: } lbarx RT,RA,RB,0) \\
lharx RT,RA,RB & \quad (\text{equivalent to: } lharx RT,RA,RB,0) \\
lwarx RT,RA,RB & \quad (\text{equivalent to: } lwarx RT,RA,RB,0) \\
ldarx RT,RA,RB & \quad (\text{equivalent to: } ldarx RT,RA,RB,0) \\
lqarx RT,RA,RB & \quad (\text{equivalent to: } lqarx RT,RA,RB,0)
\end{align*}
\]

A.3 Synchronize Mnemonics

The L field in the Synchronize instruction controls the scope of the synchronization function performed by the instruction. Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand. Two extended mnemonics are provided for the L=0 value in order to support Assemblers that do not recognize the sync mnemonic.

Note: sync serves as both a basic and an extended mnemonic. The Assembler will recognize a sync mnemonic with one operand as the basic form, and a sync mnemonic with no operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

\[
\begin{align*}
sync & \quad (\text{equivalent to: } sync 0) \\
msync<E> & \quad (\text{equivalent to: } sync 0) \\
lwsync & \quad (\text{equivalent to: } sync 1) \\
ptesync<S> & \quad (\text{equivalent to: } sync 2)
\end{align*}
\]

A.4 Wait Mnemonics

The WC field in the wait instruction determines the condition that causes instruction execution to resume. Extended mnemonics are provided that represent the WC value in the mnemonic rather than requiring it to be coded as a numeric operand.

Note: wait serves as both a basic and an extended mnemonic. The Assembler will recognize a wait mnemonic with one operand as the basic form, and a wait mnemonic with no operands as the extended form. In the extended form the WC operand is omitted and assumed to be 0.

\[
\begin{align*}
wait & \quad (\text{equivalent to: } wait 0) \\
waitrsv & \quad (\text{equivalent to: } wait 1) \\
waitimpl & \quad (\text{equivalent to: } wait 2)
\end{align*}
\]
Appendix B. Programming Examples for Sharing Storage

This appendix gives examples of how dependencies and the Synchronization instructions can be used to control storage access ordering when storage is shared between programs.

Many of the examples use extended mnemonics (e.g., bne, bne-, cmpw) that are defined in Appendix E of Book I.

Many of the examples use the Load And Reserve and Store Conditional instructions, in a sequence that begins with a Load And Reserve instruction and ends with a Store Conditional instruction (specifying the same storage location as the Load Conditional) followed by a Branch Conditional instruction that tests whether the Store Conditional instruction succeeded.

In these examples it is assumed that contention for the shared resource is low; the conditional branches are optimized for this case by using “+” and “-” suffixes appropriately.

The examples deal with words; they can be used for doublewords by changing all word-specific mnemonics to the corresponding doubleword-specific mnemonics (e.g., lwarx to ldarx, cmpw to cmpd).

In this appendix it is assumed that all shared storage locations are in storage that is Memory Coherence Required, and that the storage locations specified by Load And Reserve and Store Conditional instructions are in storage that is neither Write Through Required nor Caching Inhibited.

B.1 Atomic Update Primitives

This section gives examples of how the Load And Reserve and Store Conditional instructions can be used to emulate atomic read/modify/write operations.

An atomic read/modify/write operation reads a storage location and writes its next value, which may be a function of its current value, all as a single atomic operation. The examples shown provide the effect of an atomic read/modify/write operation, but use several instructions rather than a single atomic instruction.

Fetch and No-op

The “Fetch and No-op” primitive atomically loads the current value in a word in storage.

In this example it is assumed that the address of the word to be loaded is in GPR 3 and the data loaded are returned in GPR 4.

loop:
  lwarx r4,0,r3  #load and reserve
  stwcx. r4,0,r3  #store old value if # still reserved
  bne-  loop  #loop if lost reservation

Note:

1. The stwcx, if it succeeds, stores to the target location the same value that was loaded by the preceding lwarx. While the store is redundant with respect to the value in the location, its success ensures that the value loaded by the lwarx is still the current value at the time the stwcx. is executed.

Fetch and Store

The “Fetch and Store” primitive atomically loads and replaces a word in storage.

In this example it is assumed that the address of the word to be loaded and replaced is in GPR 3, the new value is in GPR 4, and the old value is returned in GPR 5.

loop:
  lwarx r4,0,r3  #load and reserve
  stwcx. r4,0,r3  #store new value if # still reserved
  bne-  loop  #loop if lost reservation
Fetch and Add

The “Fetch and Add” primitive atomically increments a word in storage.

In this example it is assumed that the address of the word to be incremented is in GPR 3, the increment is in GPR 4, and the old value is returned in GPR 5.

```assembly
loop:
  lwarx r5,0,r3 #load and reserve
  add r0,r4,r5 #increment word
  stwcx. r0,0,r3 #store new value if still res’ved
  bne- loop #loop if lost reservation
```

Fetch and AND

The “Fetch and AND” primitive atomically ANDs a value into a word in storage.

In this example it is assumed that the address of the word to be ANDed is in GPR 3, the value to AND into it is in GPR 4, and the old value is returned in GPR 5.

```assembly
loop:
  lwarx r5,0,r3 #load and reserve
  and r0,r4,r5 #AND word
  stwcx. r0,0,r3 #store new value if still res’ved
  bne- loop #loop if lost reservation
```

Test and Set

This version of the “Test and Set” primitive atomically loads a word from storage, sets the word in storage to a nonzero value if the value loaded is zero, and sets the EQ bit of CR Field 0 to indicate whether the value loaded is zero.

In this example it is assumed that the address of the word to be tested is in GPR 3, the new value (nonzero) is in GPR 4, and the old value is returned in GPR 5.

```assembly
loop:
  lwarx r5,0,r3 #load and reserve
  cmpwi r5,0 #done if word not equal to 0
  bne- exit #skip if not
  stwcx. r5,0,r3 #store new value if still res’ved
  bne- loop #loop if lost reservation
exit:
  mr r4,r6 #return value from storage
```

Compare and Swap

The “Compare and Swap” primitive atomically compares a value in a register with a word in storage. If they are equal stores the value from a second register into the word in storage, if they are unequal loads the word from storage into the first register, and sets the EQ bit of CR Field 0 to indicate the result of the comparison.

In this example it is assumed that the address of the word to be tested is in GPR 3, the comparand is in GPR 4 and the old value is returned there, and the new value is in GPR 5.

```assembly
loop:
  lwarx r6,0,r3 #load and reserve
  cmpw r4,r6 #1st 2 operands equal?
  bne- exit #skip if not
  stwcx. r5,0,r3 #store new value if still res’ved
  bne- loop #loop if lost reservation
exit:
  mr r4,r6 #return value from storage
```

Notes:

1. The semantics given for “Compare and Swap” above are based on those of the IBM System/370 Compare and Swap instruction. Other architectures may define a Compare and Swap instruction differently.

2. “Compare and Swap” is shown primarily for pedagogical reasons. It is useful on machines that lack the better synchronization facilities provided by lwarx and stwcx. A major weakness of a System/370-style Compare and Swap instruction is that, although the instruction itself is atomic, it checks only that the old and current values of the word being tested are equal, with the result that programs that use such a Compare and Swap to control a shared resource can err if the word has been modified and the old value subsequently restored. The sequence shown above has the same weakness.

3. In some applications the second bne- instruction and/or the mr instruction can be omitted. The bne- is needed only if the application requires that if the EQ bit of CR Field 0 on exit indicates “not equal” then (r4) and (r6) are in fact not equal. The mr is needed only if the application requires that if the comparands are not equal then the word from storage is loaded into the register with which it was compared (rather than into a third register). If either or both of these instructions is omitted, the resulting Compare and Swap does not obey System/370 semantics.
B.2 Lock Acquisition and Release, and Related Techniques

This section gives examples of how dependencies and the Synchronization instructions can be used to implement locks, import and export barriers, and similar constructs.

B.2.1 Lock Acquisition and Import Barriers

An “import barrier” is an instruction or sequence of instructions that prevents storage accesses caused by instructions following the barrier from being performed before storage accesses that acquire a lock have been performed. An import barrier can be used to ensure that a shared data structure protected by a lock is not accessed until the lock has been acquired. A sync instruction can be used as an import barrier, but the approaches shown below will generally yield better performance because they order only the relevant storage accesses.

B.2.1.1 Acquire Lock and Import Shared Storage

If lwarx and stwcx instructions are used to obtain the lock, an import barrier can be constructed by placing an isync instruction immediately following the loop containing the lwarx and stwcx. The following example uses the “Compare and Swap” primitive to acquire the lock.

In this example it is assumed that the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, the value to which the lock should be set is in GPR 5, the old value of the lock is returned in GPR 6, and the address of the shared data structure is in GPR 9.

```assembly
loop:
lwarx r6,0,r3,1 #load lock and reserve
cmpw r4,r6    #skip ahead if
bne- wait     # lock not free
stwcx r5,0,r3 #try to set lock
bne- loop     #loop if lost reservation
isync         #import barrier
lwz r7,data1(r9)#load shared data
.
wait...        #wait for lock to free
```

The hint provided with lwarx indicates that after the program acquires the lock variable (i.e. stwcx is successful), it will release it (i.e. store to it) prior to another program attempting to modify it.

The second bne- does not complete until CR0 has been set by the stwcx. The stwcx does not set CR0 until it has completed (successfully or unsuccessfully). The lock is acquired when the stwcx completes successfully. Together, the second bne- and the subsequent isync create an import barrier that prevents the load from “data1” from being performed until the branch has been resolved not to be taken.

If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, an lwsync instruction can be used instead of the isync instruction. If lwsync is used, the load from “data1” may be performed before the stwcx.. But if the stwcx. fails, the second branch is taken and the lwarx is re-executed. If the stwcx. succeeds, the value returned by the load from “data1” is valid even if the load is performed before the stwcx., because the lwsync ensures that the load is performed after the instance of the lwarx that created the reservation used by the successful stwcx..

B.2.1.2 Obtain Pointer and Import Shared Storage

If lwarx and stwcx instructions are used to obtain a pointer into a shared data structure, an import barrier is not needed if all the accesses to the shared data structure depend on the value obtained for the pointer. The following example uses the “Fetch and Add” primitive to obtain and increment the pointer.

In this example it is assumed that the address of the pointer is in GPR 3, the value to be added to the pointer is in GPR 4, and the old value of the pointer is returned in GPR 5.

```assembly
loop:
lwarx r5,0,r3 #load pointer and reserve
add r0,r4,r5 #increment the pointer
stwcx r0,0,r3 #try to store new value
bne- loop   #loop if lost reservation
lwz r7,data1(r9) #load shared data
```

The load from “data1” cannot be performed until the pointer value has been loaded into GPR 5 by the lwarx. The load from “data1” may be performed before the stwcx.. But if the stwcx. fails, the branch is taken and the value returned by the load from “data1” is discarded. If the stwcx. succeeds, the value returned by the load from “data1” is valid even if the load is performed before the stwcx., because the load uses the pointer value returned by the instance of the lwarx that created the reservation used by the successful stwcx..

An isync instruction could be placed between the bne- and the subsequent lwz, but no isync is needed if all accesses to the shared data structure depend on the value returned by the lwarx.
B.2.2 Lock Release and Export Barriers

An "export barrier" is an instruction or sequence of instructions that prevents the store that releases a lock from being performed before stores caused by instructions preceding the barrier have been performed. An export barrier can be used to ensure that all stores to a shared data structure protected by a lock will be performed with respect to any other processor before the store that releases the lock is performed with respect to that processor.

B.2.2.1 Export Shared Storage and Release Lock

A \texttt{sync} instruction can be used as an export barrier independent of the storage control attributes (e.g., presence or absence of the Caching Inhibited attribute) of the storage containing the shared data structure. Because the lock must be in storage that is neither Write Through Required nor Caching Inhibited, if the shared data structure is in storage that is Write Through Required or Caching Inhibited a \texttt{sync} instruction must be used as the export barrier.

In this example it is assumed that the shared data structure is in storage that is Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

\begin{verbatim}
  stw r7, data1(r9) #store shared data (last)
  sync          #export barrier
  stw r4, lock(r3) #release lock
\end{verbatim}

The \texttt{sync} ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the \texttt{sync} have been performed with respect to that processor.

B.2.2.2 Export Shared Storage and Release Lock using lwsync

If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, \texttt{lwsync} instruction can be used as the export barrier. Using \texttt{lwsync} rather than \texttt{sync} will yield better performance in most systems.

In this example it is assumed that the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

\begin{verbatim}
  stw r7, data1(r9) #store shared data (last)
  lwsync          #export barrier
  stw r4, lock(r3) #release lock
\end{verbatim}

The \texttt{lwsync} ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the \texttt{lwsync} have been performed with respect to that processor.

B.2.3 Safe Fetch

If a load must be performed before a subsequent store (e.g., the store that releases a lock protecting a shared data structure), a technique similar to the following can be used.

In this example it is assumed that the address of the storage operand to be loaded is in GPR 3, the contents of the storage operand are returned in GPR 4, and the address of the storage operand to be stored is in GPR 5.

\begin{verbatim}
  lwz r4, 0(r3) #load shared data
  cmpw r4, r4  #set CR0 to 'equal'
  bne- $-8    #branch never taken
  stw r7, 0(r5) #store other shared data
\end{verbatim}

An alternative is to use a technique similar to that described in Section B.2.1.2, by causing the \texttt{stw} to depend on the value returned by the \texttt{lwz} and omitting the \texttt{cmpw and bne-}. The dependency could be created by ANDing the value returned by the \texttt{lwz} with zero and then adding the result to the value to be stored by the \texttt{stw}. If both storage operands are in storage that is neither Write Through Required nor Caching Inhibited, another alternative is to replace the \texttt{cmpw and bne-} with an \texttt{lwsync} instruction.
Appendix B. Programming Examples for Sharing Storage

B.3 List Insertion

This section shows how the `lwarx` and `stwcx` instructions can be used to implement simple insertion into a singly linked list. (Complicated list insertion, in which multiple values must be changed atomically, or in which the correct order of insertion depends on the contents of the elements, cannot be implemented in the manner shown below and requires a more complicated strategy such as using locks.)

The “next element pointer” from the list element after which the new element is to be inserted, here called the “parent element”, is stored into the new element, so that the new element points to the next element in the list; this store is performed unconditionally. Then the address of the new element is conditionally stored into the parent element, thereby adding the new element to the list.

In this example it is assumed that the address of the parent element is in GPR 3, the address of the new element is in GPR 4, and the next element pointer is at offset 0 from the start of the element. It is also assumed that the next element pointer of each list element is in a reservation granule separate from that of the next element pointer of all other list elements.

```
loop:
lwarx r2,0,r3 #get next pointer
stw r2,0(r4)#store in new element
lwsync or sync #order stw before stwcx
stwcx. r4,0,r3 #add new element to list
bne- loop #loop if stwcx. failed
```

In the preceding example, if two list elements have next element pointers in the same reservation granule then, in a multiprocessor, “livelock” can occur. (Livelock is a state in which processors interact in a way such that no processor makes forward progress.)

If it is not possible to allocate list elements such that each element’s next element pointer is in a different reservation granule, then livelock can be avoided by using the following, more complicated, sequence.

```
lwz r2,0(r3)#get next pointer
loop1:
mr r5,r2 #keep a copy
stw r2,0(r4)#store in new element
sync #order stw before stwcx.
and before lwarx
lwarx r2,0,r3 #try again, reserving
cmpwi r2,0 #  (likely to succeed)
bne- loop
stwcx.r4,0,r3 #try to store non-0
bne- loop #loop if lost reserv’n
```

B.4 Notes

The following notes apply to Section B.1 through Section B.3.

1. To increase the likelihood that forward progress is made, it is important that looping on `lwarx/stwcx.` pairs be minimized. For example, in the “Test and Set” sequence shown in Section B.1, this is achieved by testing the old value before attempting the store; were the order reversed, more `stwcx.` instructions might be executed, and reservations might more often be lost between the `lwarx` and the `stwcx.`

2. The manner in which `lwarx` and `stwcx.` are communicated to other processors and mechanisms, and between levels of the storage hierarchy within a given processor, is implementation-dependent. In some implementations performance may be improved by minimizing looping on a `lwarx` instruction that fails to return a desired value. For example, in the “Test and Set” sequence shown in Section B.1, if the programmer wishes to stay in the loop until the word loaded is zero, he could change the “bne- exit” to “bne- loop”. However, in some implementations better performance may be obtained by using an ordinary Load instruction to do the initial checking of the value, as follows.

```
loop:
lwz r5,0(r3)#load the word
cmplwi r5,0 #loop back if word
bne- loop #  not equal to 0
lwarx r5,0,r3 #try again, reserving
lwarx r5,0 # (likely to succeed)
bne- loop
stwcx.r4,0,r3 #try to store non-0
bne- loop #loop if lost reserv’n
```

3. In a multiprocessor, livelock is possible if there is a `store` instruction (or any other instruction that can clear another processor’s reservation; see Section 1.7.3.1) between the `lwarx` and the `stwcx.` of a `lwarx/stwcx.` loop and any byte of the storage location specified by the Store is in the reservation granule. For example, the first code sequence shown in Section B.3 can cause livelock if two list elements have next element pointers in the same reservation granule.

B.5 Transactional Lock Elision

[Category: Transactional Memory]

This section illustrates the use of the Transactional Memory facility to implement transactional lock elision (TLE), in which lock-based critical sections are speculatedly executed as a transaction without first acquiring a lock. This locking protocol is an alternative to the rou-
tines described above, yielding increased concurrency when the lock that guards a critical section is frequently unnecessary.

### B.5.1 Enter Critical Section

The following example shows the entry point to a critical section using transactional lock elision. The entry code starts a transaction using the `tbegin` instruction and checks whether the transaction was aborted or not. If not, it checks whether the lock is free or not. If the lock is found to be free, the thread proceeds to execute the critical section.

In this example it is assumed that the address of the lock is in GPR 3, and the value indicating that the lock is free is in GPR 4. The handling of cases of transaction abort and busy lock are described in subsequent examples.

```assembly
tle_entry:
    tbegin.            #Start TLE transaction
    beq- tle_abort     #Handle TLE transaction abort
    lwz r6,0(r3)       #Read lock
    cmpw r6,r4         #Check if lock is free
    bne- busy_lock     #If not, handle lock busy case

    critical_section1:
```

### B.5.2 Handling Busy Lock

In the event that the lock is already held, by either another thread or the current thread, the transaction is aborted using the `tabort` instruction, using a software-defined code `TLE_BUSY_LOCK` indicating the cause of the abort. The abort returns control to the `beq` following `tbegin`, in the critical section entrance sequence, allowing for an abort handler to react appropriately.

```assembly
busy_lock:
    li r3, TLE_BUSY_LOCK
    tabort r3            #Abort TLE transaction
```

### B.5.3 Handling TLE Abort

A TLE transaction may fail for one of a variety of causes, persistent and transient. Persistent causes are certain—or at least highly likely—to cause future attempts to execute the same transaction to fail. However, for transient causes, it is possible that the failure cause may not be re-encountered in a subsequent attempt. Thus, persistent aborts are handled by taking a non-transactional path that involves the actual acquisition of the lock, while transient aborts retry the critical section using TLE.

The following example illustrates the handling of aborts in TLE. It is assumed that the address of the lock is in GPR 3. The immediate value of the `andis` instruction selects the Failure Persistent bit in the upper half of "TEXASR to be tested.

```assembly
tle_abort:
    mspr r4, TEXASRU  # Read high-order half
    # of "TEXASR
    andis. r5,r4,0x0100 # determine whether failure
    # is likely to be persistent
    bne tle_acquire_lock #Persistent, acquire lock
    #enter critical sec
    b tle_entry         #Transient, try TLE again
```

This example can be extended to keep track of the number of transient aborts and fall back on the acquisition of the lock after the number of transient failures reaches some threshold. It can also be extended to handle reentrant locks. Acquisition of TLE locks is described in a subsequent example.

### B.5.4 TLE Exit Section Critical Path

The following example illustrates the instruction sequence used to exit a TLE critical section. The CR0 value set by `tend` indicates whether the current thread was in a transaction. If so, the exited critical section was entered speculatively, and the transaction is ended. If not, the execution takes a path to release the lock.

Release of an acquired TLE lock is described in a subsequent example.

```assembly
tle_exit:
    tend.                   #End the current trans-
    #action, if any
    bng- tle_release_lock   #Release lock, if was
    #not in a transaction
```

### B.5.5 Acquisition and Release of TLE Locks

The steps for acquiring and releasing a lock associated with a TLE critical section are nearly identical to those for acquiring and releasing conventional locks that are not elided, as described in Section B.2. The only difference is special care must be taken to prevent loads and stores inside the critical section protected by the lock from being performed before the `Store Conditional` instruction to the lock variable.

The `isync` from the `Acquire Lock and Import Shared Storage` sequence described in Section B.2.1.1 is insufficient for ordering subsequent instructions. Instead, a
stronger storage access ordering instruction is needed. The following example shows the resulting steps for acquiring a TLE lock, replacing the `isync` instruction with a `sync` instruction. In this example it is assumed that the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, the value to which the lock should be set is in GPR 5.

tle_acquire_lock:
  lwax r10,0,r3,1       #Load lock and reserve
  cmpw r4,r10            #Skip ahead if
  bne- wait              #Lock not free
  stwcx. r5,0,r3         #Try to set lock
  bne- tle_acquire_lock  #Loop if lost reservation
  sync                   #Import barrier for TLE

critical_section1:

The instruction sequence necessary for the release of a TLE lock is identical to the conventional lock release sequence, where `lwsync` is sufficient to prevent the store that releases the lock from being performed before the loads and stores in the critical section protected by the lock.
Book III-S:

Power ISA Operating Environment Architecture - Server Environment [Category: Server]
Chapter 1. Introduction

1.1 Overview

Chapter 1 of Book I describes computation modes, document conventions, a general systems overview, instruction formats, and storage addressing. This chapter augments that description as necessary for the Power ISA Operating Environment Architecture.

1.2 Document Conventions

The notation and terminology used in Book I apply to this Book also, with the following substitutions.

- For “system alignment error handler” substitute “Alignment interrupt”.
- For “system data storage error handler” substitute “Data Storage interrupt”, “Hypervisor Data Storage interrupt”, or “Data Segment interrupt”, as appropriate.
- For “system error handler” substitute “interrupt”.
- For “system floating-point enabled exception error handler” substitute “Floating-Point Enabled Exception type Program interrupt”.
- For “system illegal instruction error handler” substitute “Hypervisor Emulation Assistance interrupt”.
- For “system instruction storage error handler” substitute “Instruction Storage interrupt”, “Hypervisor Instruction Storage interrupt”, or “Instruction Segment interrupt”, as appropriate.
- For “system privileged instruction error handler” substitute “Privileged Instruction type Program interrupt”.
- For “system service program” substitute “System Call interrupt”.
- For “system trap handler” substitute “Trap type Program interrupt”.
- For “system Facility Unavailable error handler” substitute “Facility Unavailable interrupt” or “Hypervisor Facility Unavailable interrupt.”

1.2.1 Definitions and Notation

The definitions and notation given in Book I are augmented by the following.

- **Threaded processor, single-threaded processor, thread**
  A threaded processor implements one or more “threads”, where a thread corresponds to the Book I/II concept of “processor”. That is, the definition of “thread” is the same as the Book I definition of “processor”, and “processor” as used in Books I and II can be thought of as either a single-threaded processor or as one thread of a multi-threaded processor. The only unqualified uses of “processor” in Book III are in resource names (e.g. Processor Identification Register); such uses should be regarded as meaning “threaded processor”. The threads of a multi-threaded processor typically share certain resources, such as the hardware components that execute certain kinds of instructions (e.g., Fixed-Point instructions), certain caches, the address translation mechanism, and certain hypervisor resources.

- **real page**
  A unit of real storage that is aligned at a boundary that is a multiple of its size. The real page size is 4KB.

- **context of a program**
  The state (e.g., privilege and relocation) in which the program executes. The context is controlled by the contents of certain System Registers, such as the MSR and SDR1, of certain lookaside buffers, such as the SLB and TLB, and of the Page Table.

- **exception**
  An error, unusual condition, or external signal, that may set a status bit and may or may not cause an interrupt, depending upon whether the corresponding interrupt is enabled.

- **interrupt**
  The act of changing the machine state in response to an exception, as described in Chapter 6. “Interrupts” on page 939.
Additional exceptions to the sequential execution model, beyond those described in the section entitled “Instruction Fetching” in Book I, are the following.

- A System Reset or Machine Check interrupt may occur. The determination of whether an instruction is required by the sequential execution model is not affected by the potential occurrence of a System Reset or Machine Check interrupt. (The determination is affected by the potential occurrence of any other kind of interrupt.)

- A context-altering instruction is executed (Chapter 12. “Synchronization Requirements for Context Alterations” on page 1009). The context alteration need not take effect until the required subsequent synchronizing operation has occurred.

- A Reference and Change bit is updated by the thread. The update need not be performed with respect to that thread until the required subsequent synchronizing operation has occurred.

- A Branch instruction is executed and the branch is taken. The update of the Come-From Address Register<sup>S</sup> (see Section 8.1.1 of Book III-S) need not occur until a subsequent context synchronizing operation has occurred.

“must”
If hypervisor software violates a rule that is stated using the word “must” (e.g., “this field must be set to 0”), and the rule pertains to the contents of a hypervisor resource, to executing an instruction that can be executed only in hypervisor state, or to accessing storage in real addressing mode, the results are undefined, and may include altering resources belonging to other partitions, causing the system to “hang”, etc.

Hardware
Any combination of hard-wired implementation, emulation assist, or interrupt for software assistance. In the last case, the interrupt may be to an architected location or to an implementation-dependent location. Any use of emulation assists or interrupts to implement the architecture is implementation-dependent.

Hypervisor privileged
A term used to describe an instruction or facility that is available only when the thread is in hypervisor state.

Privileged state and supervisor mode
Used interchangeably to refer to a state in which privileged facilities are available.

Problem state and user mode
Used interchangeably to refer to a state in which privileged facilities are not available.

/, //, ///, ... denotes a field that is reserved in an instruction, in a register, or in an architected storage table.

?, ??, ???, ... denotes a field that is implementation-dependent in an instruction, in a register, or in an architected storage table.

1.2.2 Reserved Fields

Book I’s description of the handling of reserved bits in System Registers, and of reserved values of defined fields of System Registers, applies also to the SLB. Book I’s description of the handling of reserved values of defined fields of System Registers applies also to architected storage tables (e.g., the Page Table).

Some fields of certain architected storage tables may be written to automatically by the hardware, e.g., Reference and Change bits in the Page Table. When the hardware writes to such a table, the following rules are obeyed.

- Unless otherwise stated, no defined field other than the one(s) specifically being updated are modified.
- Contents of reserved fields are either preserved or written as zero.

Programming Note
Software should set reserved fields in the SLB and in architected storage tables to zero, because these fields may be assigned a meaning in some future version of the architecture.

1.3 General Systems Overview

The hardware contains the sequencing and processing controls for instruction fetch, instruction execution, and interrupt action. Most implementations also contain data and instruction caches. Instructions that the processing unit can execute fall into the following classes:

- Instructions executed in the Branch Facility
- Instructions executed in the Fixed-Point Facility
- Instructions executed in the Floating-Point Facility
- Instructions executed in the Vector Facility

Almost all instructions executed in the Branch Facility, Fixed-Point Facility, Floating-Point Facility, and Vector Facility are nonprivileged and are described in Book I. Book II may describe additional nonprivileged instructions (e.g., Book II describes some nonprivileged...
instructions for cache management). Instructions related to the privileged state, control of hardware resources, control of the storage hierarchy, and all other privileged instructions are described here or are implementation-dependent.

1.4 Exceptions

The following augments the exceptions defined in Book I that can be caused directly by the execution of an instruction:

- the execution of a floating-point instruction when MSRFP=0 (Floating-Point Unavailable interrupt)
- an attempt to modify a hypervisor resource when the thread is in privileged but non-hypervisor state (see Chapter 2), or an attempt to execute a hypervisor-only instruction (e.g., tlbie) when the thread is in privileged but non-hypervisor state
- the execution of a traced instruction (Trace interrupt)
- the execution of a Vector instruction when the vector facility is unavailable (Vector Unavailable interrupt)

1.5 Synchronization

The synchronization described in this section refers to the state of the thread that is performing the synchronization.

1.5.1 Context Synchronization

An instruction or event is context synchronizing if it satisfies the requirements listed below. Such instructions and events are collectively called context synchronizing operations. The context synchronizing operations are the isync instruction, the System Linkage instructions, the mtmsrd instructions with L=0, and most interrupts (see Section 6.4).

1. The operation causes instruction dispatching (the issuance of instructions by the instruction fetching mechanism to any instruction execution mechanism) to be halted.

2. The operation is not initiated or, in the case of isync, does not complete, until all instructions that precede the operation have completed to a point at which they have reported all exceptions they will cause.

3. The operation ensures that the instructions that precede the operation will complete execution in the context (privilege, relocation, storage protection, etc.) in which they were initiated, except that the operation has no effect on the context in which the associated Reference and Change bit updates are performed.

4. If the operation directly causes an interrupt (e.g., sc directly causes a System Call interrupt) or is an interrupt, the operation is not initiated until no exception exists having higher priority than the exception associated with the interrupt (see Section 6.8).

5. The operation ensures that the instructions that follow the operation will be fetched and executed in the context established by the operation. (This requirement dictates that any prefetched instructions be discarded and that any effects and side effects of executing them out-of-order also be discarded, except as described in Section 5.5, “Performing Operations Out-of-Order”.)

Programming Note

A context synchronizing operation is necessarily execution synchronizing; see Section 1.5.2.

Unlike the Synchronize instruction, a context synchronizing operation does not affect the order in which storage accesses are performed.

Item 2 permits a choice only for isync (and sync and ptesync; see Section 1.5.2) because all other execution synchronizing operations also alter context.
1.5.2 Execution Synchronization

An instruction is *execution synchronizing* if it satisfies items 2 and 3 of the definition of context synchronization (see Section 1.5.1). `sync` and `ptesync` are treated like `isync` with respect to item 2. The execution synchronizing instructions are `sync`, `ptesync`, the `mtmsr[d]` instructions with L=1, and all context synchronizing instructions.

**Programming Note**

Unlike a context synchronizing operation, an execution synchronizing instruction does not ensure that the instructions following that instruction will execute in the context established by that instruction. This new context becomes effective sometime after the execution synchronizing instruction completes and before or at a subsequent context synchronizing operation.
Chapter 2. Logical Partitioning (LPAR) and Thread Control

2.1 Overview

The Logical Partitioning (LPAR) facility permits threads and portions of real storage to be assigned to logical collections called partitions, such that a program executing on a thread in one partition cannot interfere with any program executing on a thread in a different partition. This isolation can be provided for both problem state and privileged state programs, by using a layer of trusted software, called a hypervisor program (or simply a “hypervisor”), and the resources provided by this facility to manage system resources. (A hypervisor is a program that runs in hypervisor state; see below.)

The number of partitions supported is implementation-dependent.

A thread is assigned to one partition at any given time. A thread can be assigned to any given partition without consideration of the physical configuration of the system (e.g., shared registers, caches, organization of the storage hierarchy), except that threads that share certain hypervisor resources may need to be assigned to the same partition; see Section 2.7. The registers and facilities used to control Logical Partitioning are listed below and described in the following subsections.

Except in the following subsections, references to the “operating system” in this document include the hypervisor unless otherwise stated or obvious from context.

2.2 Logical Partitioning Control Register (LPCR)

The layout of the Logical Partitioning Control Register (LPCR) is shown in Figure 1 below.

![Logical Partitioning Control Register](image)

The contents of the LPCR control a number of aspects of the operation of the thread with respect to a logical partition. Below are shown the bit definitions for the LPCR.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:3</td>
<td>Virtualization Control (VC)</td>
</tr>
<tr>
<td>0:1</td>
<td>Virtualized Partition Memory (VPM)</td>
</tr>
</tbody>
</table>

This field controls whether VPM mode is enabled as specified below. (See Section 5.7.3.4 and Section 5.7.2, “Virtualized Partition Memory (VPM) Mode” for additional information on VPM mode.)

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>This bit controls whether VPM mode is enabled when address translation is disabled</td>
</tr>
<tr>
<td></td>
<td>0 - VPM mode disabled</td>
</tr>
<tr>
<td></td>
<td>1 - VPM mode enabled</td>
</tr>
</tbody>
</table>
1 This bit controls whether VPM mode is enabled when address translation is enabled.
   0 - VPM mode disabled
   1 - VPM mode enabled

2 **Ignore SLB Large Page Specification (ISL)**
   Controls whether ISL mode is enabled as specified below.
   0 - ISL mode disabled
   1 - ISL mode enabled
   When ISL mode is enabled and address translation is enabled, address translation is performed as if the contents of SLB_LILP were 0b000. When address translation is disabled, the setting of the ISL bit has no effect. ISL mode has no effect on SLB, TLB, and ERAT entry invalidations caused by slbie, slbia, tlbia, tlbie, and slbie.

3 **Key-Based Virtualization (KBV)**
   Controls whether Key-Based Virtualization is enabled as specified below.
   0 - KBV is disabled
   1 - KBV is enabled
   When KBV is enabled, Virtual Page Class Key Storage Protection exceptions that occur on operand accesses when VPM1=0 cause Hypervisor Data Storage interrupts.

**Programming Note**

Key-Based Virtualization provides an efficient means for the hypervisor to intercept storage references, e.g., MMIO, that must be emulated. (The corresponding behavior for instruction fetching is not desired.) Virtual Page Class Key Storage Protection exceptions not handled by the hypervisor should be reflected to the operating system at its Data Storage interrupt vector with the hypervisor having set DSISR42.

4:8 Reserved

9:11 **Default Prefetch Depth (DPFD)**
   The DPFD field is used as the default prefetch depth for data stream prefetching when DSCR_PDPF=0; see page 764.

12:16 **Virtual Real Mode Area Segment Descriptor (VRMASD)**
   When address translation is disabled and VPM0=1, the contents of this field specify the L and LP fields of the segment descriptor that apply for storage references to the virtualized real mode area (VRMA). See Section 5.7.3.4 for additional information. The definitions and allowed values of the L and LP fields are the same as for the corresponding fields in the segment descriptor. (See Section 5.7.7.) If VPM0=0 or address translation is enabled, the setting of the VRMASD has no effect.

**Bit Description**

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Virtual Page Size Selector Bit 0 (L)</td>
</tr>
<tr>
<td>1:2</td>
<td>Reserved</td>
</tr>
<tr>
<td>3:4</td>
<td>Virtual Page Size Selector Bits 1:2 (LP)</td>
</tr>
</tbody>
</table>

**Programming Note**

Specifying that LILP=0b000 in the VRMASD field when VPM mode is enabled has the same effect on address translation when translation is disabled as enabling ISL mode when translation is enabled.

ISL mode is needed when translation is enabled because translation uses the SLB, and the contents of the SLB are accessible to the operating system and should not be modified by the hypervisor. ISL mode is not needed when translation is disabled since translation uses the VRMASD, which is not visible to the operating system and is in complete control of the hypervisor.

17:33 Reserved

34:37 **Real Mode Limit Selector (RMLS)**
   The RMLS field specifies the largest effective address that can be used by partition software when address translation is disabled. The valid RMLS values are implementation-dependent, and each value corresponds to a maximum effective address of $2^m$, where $m$ has a minimum value of 12 and a maximum value equal to the number of bits in the real address size supported by the implementation.

38 **Interrupt Little-Endian (ILE)**
   The contents of the ILE bit are copied into MSR_LE by interrupts that set MSR_HV to 0 (see Section 6.5), to establish the Endian mode for the interrupt handler.

39:40 **Alternate Interrupt Location (AIL)**
   Controls the effective address offset of the interrupt handler and the relocation mode in which it begins execution for all interrupts except Machine Check, System Reset, and Hypervisor Maintenance.
   0 The interrupt is taken with MSR_IR_DR = 0b00 and no effective address offset.
Reserved

2 The interrupt is taken with MSR<sub>IR</sub> = 0b11 and an effective address offset of 0x0000_0000_0001_8000.

3 The interrupt is taken with MSR<sub>IR</sub> = 0b11 and an effective address offset of 0xc000_0000_0000_4000.

Interruptions that cause a transition from MSR<sub>HV</sub>=0 to MSR<sub>HV</sub>=1, or that occur when MSR<sub>IR</sub>=0 or MSR<sub>DR</sub>=0, are always taken as if LPC<sub>AIL</sub>=0.

---

**Programming Note**

One of the purposes of the AIL field is to provide relocation for interrupts that occur while an application is running with MSR<sub>HV</sub> PR=0b11 under a "bare metal" operating system (i.e., an operating system that runs in hypervisor state), such as KVM.

41:44 Reserved

45 **Online** (ONL)

0 The PURR and SPURR do not increment.
1 The PURR and SPURR increment.

---

**Programming Note**

Typically, the hypervisor sets the ONL bit to 0 when the thread is not in a power saving mode, is not performing useful work, and is available for use. The hypervisor may take the state of the ONL bit into account when making course-grain load balancing and power management decisions.

46 Reserved

47:51 **Power-saving mode Exit Cause Enable** (PECE)

47 <S.PC> If PECE<sub>0</sub> = 1 when a Power-Saving Mode instruction is executed, Directed Privileged Doorbell exceptions are enabled to cause exit from power-saving mode; otherwise Directed Privileged Doorbell exceptions are disabled from causing exit from power-saving mode.

48 <S.PC> If PECE<sub>1</sub> = 1 when a Power-Saving Mode instruction is executed, Directed Hypervisor Doorbell exceptions are enabled to cause exit from power-saving mode; otherwise Directed Hypervisor Doorbell exceptions are disabled from causing exit from power-saving mode.

49 If PECE<sub>2</sub> = 1 when a Power-Saving Mode instruction is executed, External exceptions are enabled to cause exit from power-saving mode; otherwise External exceptions are disabled from causing exit from power-saving mode.

50 If PECE<sub>3</sub> = 1 when a Power-Saving Mode instruction is executed, Decrementer exceptions are enabled to cause exit from power-saving mode; otherwise Decrementer exceptions are disabled from causing exit from power-saving mode. (In sleep and rwwinkle power-saving levels, Decrementer exceptions do not occur if the state of the Decrementer is not maintained and updated as if the thread was not in power-saving mode.)

51 If PECE<sub>4</sub>=1 when a Power-Saving Mode instruction is executed, Machine Check, Hypervisor Maintenance, and certain implementation-specific exceptions are enabled to cause exit from power-saving mode; otherwise Machine Check, Hypervisor Maintenance, and the same implementation-specific exceptions are disabled from causing exit from power-saving mode.

It is implementation-specific whether the exceptions enabled by the PECE field cause exit from sleep and rwwinkle power-saving levels. See Section 6.5.1 and Section 6.5.2 for additional information about exit from power-saving mode.

52 **Mediated External Exception Request** (MER)

0 A Mediated External exception is not requested.
1 A Mediated External exception is requested.

The exception effects of this bit are said to be consistent with the contents of this bit if one of the following statements is true.

- LPC<sub>MER</sub> = 1 and a Mediated External exception exists.
- LPC<sub>MER</sub> = 0 and a Mediated External exception does not exist.

A context synchronizing instruction or event that is executed or occurs when LPC<sub>MER</sub> = 0 ensures that the exception effects of LPC<sub>MER</sub> are consistent with the contents of LPC<sub>MER</sub>. Otherwise, when an instruction changes the contents of LPC<sub>MER</sub>, the exception effects of LPC<sub>MER</sub> become consistent with the new contents of LPC<sub>MER</sub> reasonably soon after the change.

---

The exception effects of this bit are said to be consistent with the contents of this bit if one of the following statements is true.
2.3 Real Mode Offset Register (RMOR)

The layout of the Real Mode Offset Register (RMOR) is shown in Figure 2 below.

<table>
<thead>
<tr>
<th>Bits</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>63:4</td>
<td>RMO</td>
<td>Real Mode Offset</td>
</tr>
</tbody>
</table>

Figure 2. Real Mode Offset Register

All other fields are reserved.

The supported RMO values are the non-negative multiples of $2^s$, where $2^s$ is the smallest implementation-dependent limit value representable by the contents of the Real Mode Limit Selector field of the LPCR.

The contents of the RMOR affect how some storage accesses are performed as described in Section 5.7.3 on page 891 and Section 5.7.4 on page 895.

2.4 Hypervisor Real Mode Offset Register (HRMOR)

The layout of the Hypervisor Real Mode Offset Register (HRMOR) is shown in Figure 3 below.

<table>
<thead>
<tr>
<th>Bits</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>63:4</td>
<td>HRMO</td>
<td>Real Mode Offset</td>
</tr>
</tbody>
</table>

Figure 3. Hypervisor Real Mode Offset Register

All other fields are reserved.

The supported HRMO values are the non-negative multiples of $2^r$, where $r$ is an implementation-dependent value and $12 \leq r \leq 26$.

The contents of the HRMOR affect how some storage accesses are performed as described in Section 5.7.3 on page 891 and Section 5.7.4 on page 895.

See Section 6.5 on page 950 for a description of how the setting of LPES affects the processing of interrupts.
2.5 Logical Partition Identification Register (LPIDR)

The layout of the Logical Partition Identification Register (LPIDR) is shown in Figure 4 below.

<table>
<thead>
<tr>
<th>Bits</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:63</td>
<td>LPID</td>
<td>Logical Partition Identifier</td>
</tr>
</tbody>
</table>

Figure 4. Logical Partition Identification Register

The contents of the LPIDR identify the partition to which the thread is assigned, affecting operations necessary to manage the coherency of some translation looksaside buffers (see Section 5.10.1 and Chapter 12.). The number of LPIDR bits supported is implementation-dependent.

Programming Note

On some implementations, software must prevent the execution of a `tlbie` instruction with an LPID operand value which matches the contents of another thread’s LPIDR that is being modified or is the same as the new value being written to the LPIDR. This restriction can be met with less effort if one partition identity is used only on threads on which no `tlbie` instruction is ever executed. This partition can be thought of as the transfer partition used exclusively to move a thread from one partition to another.

2.6 Processor Compatibility Register (PCR) [Category: Processor Compatibility]

The layout of the Processor Compatibility Register (PCR) is shown in Figure 5 below.

![Figure 5. Processor Compatibility Register](image)

A PCR bit may also determine how an instruction field value is interpreted or may define other behavior as specified in the bit definitions below.

- Instructions are treated as illegal instructions,
- SPRs are treated as if they were not defined for the implementation,
- The “reserved SPRs” (see Section 1.3.3 of Book I) are treated as not defined for the implementation,
- Fields in instructions are treated as if they were 0s,
- bits in system registers read back 0s, and `mtspr` operations have no effect on their values.
- `rfebb` instructions have the same effect on bits in system registers that they would if the bits were available.

Architecture Note

When a bit in a system register is made unavailable by the PCR, `mtspr` operations performed on the register in problem state have no effect on the value of the bit regardless of the privilege state in which the register may subsequently be read. When transactional memory is made unavailable by the PCR, however, `rfebb` instructions executed in problem state have the same effect on MSR_T as they would if transactional memory were available. This behavior is specified so that illegal transaction state transitions resulting from changes to BESCRTS made by privileged code will cause TM Bad Thing interrupts when `rfebb` is executed, thereby facilitating program debug.

The PCR has no effect on the setting of the MSR and [H]SR1 by interrupts, and by the [H]rtd and `mtmsr[d]` instructions, except as specified elsewhere in this section.
When facilities that have enable bits in the MSR, FSCR, HFSCR, or MMCR0 are made unavailable by the value in the PCR, they become unavailable in problem state as specified above regardless of whether they are enabled by the corresponding MSR, FSCR, HFSCR, or MMCR0 bit; facility availability interrupts (e.g. [Hypervisor] Facility Available, Vector Unavailable, etc.) do not occur as a result of problem-state accesses even if the corresponding field in the MSR, HFSCR, or MMCR0 makes them unavailable in problem state.

Programming Note

Because the PCR does not prevent mtspr, rfscv, [h]rfid, and mtmsr[d] instructions from setting bits in system registers that the PCR will make unavailable after a transition to problem state, these instructions may cause interrupts in a variety of unexpected ways. For example, consider an operating system that sets SRR1 such that rfid returns to problem state with MSR[TS] nonzero. A TM Bad Thing interrupt will result, despite that TM is made unavailable by the PCR.

Similarly, the PCR does not prevent rfebb instructions from setting bits in system registers that the PCR has made unavailable in problem state, and thus changes to BESCR_T made by privileged code have the potential to subsequently cause illegal transaction state transitions when rfebb is executed in problem state, resulting in the occurrence of TM Bad Thing interrupts.

When facilities that have enable bits in the MSR, FSCR, HFSCR, or MMCR0 are made unavailable by the value in the PCR, they become unavailable in problem state as specified above regardless of whether they are enabled by the corresponding MSR, FSCR, HFSCR, or MMCR0 bit; facility availability interrupts (e.g. [Hypervisor] Facility Available, Vector Unavailable, etc.) do not occur as a result of problem-state accesses even if the corresponding field in the MSR, HFSCR, or MMCR0 makes them unavailable in problem state.

Programming Note

Facilities that can be disabled in problem state by the PCR that also have enable bits in either the MSR or HFSCR include Transactional Memory, the BHRB instructions, event-based branch instructions, TAR, DSCR at SPR 3, SIER, MMCR2, the event-based branch instructions, and certain Floating-Point, Vector, and VSX instructions. When any of these facilities are made unavailable in problem state by the PCR, the corresponding [Hypervisor] Facility Unavailable, Floating-Point Unavailable, Vector, or VSX unavailable interrupts do not occur when the facility is accessed in problem state. Note, however, that the PCR does not affect privileged accesses, and thus any Hypervisor Facility Unavailable, Floating-Point Unavailable, Vector unavailable, or VSX unavailable interrupts that are specified to occur as a result of privileged accesses occur regardless of the PCR value.

The bit definitions for the PCR are shown below.

<table>
<thead>
<tr>

Table 1: Category: VSX and Vector Instructions Controlled by the v2.06 Bit
0 The listed instructions, facilities, and behaviors are available in problem state.
1 The listed instructions, facilities, and behaviors are unavailable in problem state.

Version 2.05 (v2.05)

This bit controls the availability, in problem state, of the following instructions, facilities, and behaviors that were newly available in problem state in the version of the architecture subsequent to Version 2.05.
- AMR access using SPR 13
- addg6s
- bperm
- cdtdbc, cbcdtb
- dcffix[.]
- divide[a][.], divideu[a][.], dividwe[a][.], dividweu[a][.]
- isel
- ifiwxz [Category: Floating-Point: Phased-In]
- fctidu[.], fctiduz[.], fctiwnu[.], fctiwuz[.], fcfidu[.], fcfidus[.], ftdiv, fsqrt [Category: Floating-Point: Phased-In]
- ldrbx, stdbrx [Category: 64-bit]
- popcntw, popcntd
- All facilities in Category: VSX

0 The listed instructions, facilities, and behaviors are available in problem state.
1 The listed instructions, facilities, and behaviors are unavailable in problem state.

If this bit is set to 1, then the v2.06 bit must also be set to 1.

Reserved

The initial state of the PCR is all 0s.

Programming Note

Because the PCR has no effect on privileged instructions except as specified above, privileged instructions that are available on newer implementations but not available on older implementations will behave differently when the thread is in problem state. On older implementations, either an Illegal Instruction type Program interrupt or a Hypervisor Emulation Assistance interrupt will occur because the instruction is undefined; on newer implementations, a Privileged Instruction Program interrupt will occur because the instruction is implemented. (On older implementations the interrupt will be an Illegal Instruction type Program interrupt if the implementation complies with a version of the architecture that precedes V. 2.05, or complies with V. 2.05 and does not support the Hypervisor Emulation Assistance category, and will be a Hypervisor Emulation Assistance interrupt otherwise.)

In future versions of the architecture, in general the lowest-order reserved bit of the PCR will be used to control the availability of the instructions and related resources that are new in that version of the architecture; the name of the bit will correspond to the previous version of the architecture (i.e. the newest version in which the instructions and related resources were not available).

In these future versions of the architecture, there will be a requirement that if any bit of the low-order defined bits is set to 1 then all higher-order bits of the defined low-order bits must also be set to 1, and the architecture version with which the implementation appears to comply, in problem state, will be the version corresponding to the name of the lowest-order 1 bit in the set of defined low-order PCR bits, or the current architecture version if none of these bits are 1. Also, in general the highest-order reserved bits will be used to control the availability of sets of instructions and related resources having the requirement that their availability be independent of versions of the architecture.

2.7 Other Hypervisor Resources

In addition to the resources described above, all hypervisor privileged instructions as well as the following resources are hypervisor resources, accessible to software only when the thread is in hypervisor state except as noted below.

- All implementation-specific resources except for privileged non-hypervisor implementation-specific SPRs. (See Section 4.4.4 for the list of the implementation-specific SPRs that are allowed to be privileged non-hypervisor SPRs.) Implementa-
tion-specific registers include registers (e.g., “HID” registers) that control hardware functions or affect the results of instruction execution. Examples include resources that disable caches, disable hardware error detection, set breakpoints, control power management, or significantly affect performance.

- ME bit of the MSR
- SPRs defined as hypervisor-privileged in Section 4.4.4. (Note: Although the Time Base, the PURR, and the SPURR can be altered only by a hypervisor program, the Time Base can be read by all programs and the PURR and SPURR can be read when the thread is in privileged state.)

The contents of a hypervisor resource can be modified by the execution of an instruction (e.g., mtspr) only in hypervisor state (MSRHVPR = 0b10). An attempt to modify the contents of a given hypervisor resource, other than MSRME, in privileged but non-hypervisor state (MSRHVPR = 0b00) causes a Privileged Instruction type Program interrupt. An attempt to modify MSRME in privileged but non-hypervisor state is ignored (i.e., the bit is not changed).

### Programming Note

Because the SPRs listed above are privileged for writing, an attempt to modify the contents of any of these SPRs in problem state (MSRPR=1) using mtspr causes a Privileged Instruction type Program exception, and similarly for MSRME.

### 2.8 Sharing Hypervisor Resources

Shared SPRs are SPRs that are accessible to multiple threads. Changes to shared SPRs made by one thread are immediately readable (using mfspr) by all other threads sharing the SPR.

The LPIDR and DPDES must appear to software to be shared among threads of a sub-processor (see Section 2.9). If the implementation does not support sub-processors, the LPIDR and DPDES must be shared among all threads of the multi-threaded processor.

Certain other hypervisor resources may be shared among threads. Programs that modify these resources must be aware of this sharing, and must allow for the fact that changes to these resources may affect more than one thread.

The following resources may be shared among threads.

- RMOR (see Section 2.3)
- HRMOR (see Section 2.4)
- LPIDR (see Section 2.5)

- PCR [Category: Processor Control] (see Section 2.6)
- PVR (see Section 4.3.1)
- RPR (see Section 4.3.7)
- SDR1 (see Section 5.7.7.2)
- AMOR (see Section 5.7.9.1)
- HMEER (see Section 6.2.9)
- Time Base (see Section 7.2)
- Virtual Time Base (see Section 7.3)
- Hypervisor Decrementer (see Section 7.5)
- certain implementation-specific registers or implementation-specific fields in architected registers

The set of resources that are shared is implementation-dependent.

Threads that share any of the resources listed above, with the exception of the PVR and the HRMOR, must be in the same partition.

For each field of the LPCR, except the AIL, ONL, HDICE, and MER fields, software must ensure that the contents of the field are identical among all threads that are in the same partition and are in a state such that the contents of the field could have side effects. (E.g., software must ensure that the contents of LPCR_LPES are identical among all threads that are in the same partition and are not in hypervisor state.) For the HDICE field, software must ensure that the contents of the field are identical among all threads that share the Hypervisor Decrementer and are in a state such that the contents of the field could have side effects. There are no identity requirements for the other fields listed in the first sentence of this paragraph.

### 2.9 Sub-Processors

Hardware is allowed to sub-divide a multi-threaded processor into “sub-processors” that appear to privileged programs as multi-threaded processors with fewer threads. Such a multi-threaded processor appears to the hypervisor as a processor with a number of threads equal to the sum of all sub-processor threads, and in which the LPIDR for each sub-processor must appear to be shared among all threads of that sub-processor.

### 2.10 Thread Identification Register (TIR) [Category: Server Processor Control]

The TIR is a 64-bit read-only register that contains the thread number, which is a binary number corresponding to the thread.

For implementations that do not support sub-processors, the thread number of a thread is unique among all thread numbers of threads on the multi-threaded processor.
For implementations that support sub-processors, the value of this register depends on whether it is read in hypervisor or privileged, non-hypervisor state as follows.

- When this register is read in privileged, non-hypervisor state, the thread number is unique among all thread numbers of threads on the sub-processor.
- When this register is read in hypervisor state, the thread number is unique among all thread numbers of threads on the multi-threaded processor.

Threads are numbered sequentially, with valid values ranging from 0 to t-1, where t is the number of threads implemented. A thread for which \( TIR = n \) is referred to as “thread n.”

The layout of the TIR is shown below.

**Figure 6. Thread Identification Register**

Access to the TIR is privileged.

Since the thread number contained in this register is different if it is read in hypervisor from when it is read in privileged, non-hypervisor state in implementations that support sub-processors, the following conventions are used.

- The value returned in privileged, non-hypervisor state is referred to as the “privileged thread number.”
- The value returned in hypervisor state is referred to as the “hypervisor thread number.”

### 2.11 Hypervisor Interrupt Little-Endian (HILE) Bit

The Hypervisor Interrupt Little-Endian (HILE) bit is a bit in an implementation-dependent register or similar mechanism. The contents of the HILE bit are copied into MSR\(_{LE}\) by interrupts that set MSR\(_{HV}\) to 1 (see Section 6.5), to establish the Endian mode for the interrupt handler. The HILE bit is set, by an implementation-dependent method, during system initialization, and cannot be modified after system initialization.

The contents of the HILE bit must be the same for all threads under the control of a given instance of the hypervisor; otherwise all results are undefined.
Chapter 3. Branch Facility

3.1 Branch Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Branch Facility that are not covered in Book I.

3.2 Branch Facility Registers

3.2.1 Machine State Register

The Machine State Register (MSR) is a 64-bit register. This register defines the state of the thread. On interrupt, the MSR bits are altered in accordance with Figure 51 on page 951. The MSR can also be modified by the \texttt{mtmsr[d]}, \texttt{rfid}, and \texttt{hrfid} instructions. It can be read by the \texttt{mfmsr} instruction.

d\hline
MSR\hline
0 & 63
\end{tabular}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{machine_state_register.png}
\caption{Machine State Register}
\end{figure}

Below are shown the bit definitions for the Machine State Register.

<table>
<thead>
<tr>
<th>Bit</th>

</tr>
<tr>
<td>6:28</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
Bit & Description \\
\hline
4 & Privilege State (PR) \\
0 & 0 privileged \\
0 & 1 problem \\
1 & 0 hypervisor \\
1 & 1 problem \\
\hline
\end{tabular}
\caption{Bit Definitions for Machine State Register}
\end{table}

Hypervisor state is also a privileged state (MSR\textsubscript{PR} = 0). All references to "privileged state" in the Books include hypervisor state unless otherwise stated or if it is obvious from the context. MSR\textsubscript{HV} can be set to 1 only by the \texttt{Sys-tem Call} instruction and some interrupts. It can be set to 0 only by \texttt{rfid} and \texttt{hrfid}.

It is possible to run an operating system in an environment that lacks a hypervisor, by always having MSR\textsubscript{HV} = 1 and using MSR\textsubscript{HV} \| MSR\textsubscript{PR} = 10 for the operating system (effectively, the OS runs in hypervisor state) and MSR\textsubscript{HV} \| MSR\textsubscript{PR} = 11 for applications.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
Bit & Description \\
\hline
4 & Privilege State (PR) \\
0 & 0 privileged \\
0 & 1 problem \\
1 & 0 hypervisor \\
1 & 1 problem \\
\hline
\end{tabular}
\caption{Bit Definitions for Machine State Register}
\end{table}

Programming Note

The privilege state of the thread is determined by MSR\textsubscript{HV} and MSR\textsubscript{PR}, as follows.

<table>
<thead>
<tr>
<th>HV</th>
<th>PR</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>

0 & 1 problem |
1 & 0 hypervisor |
1 & 1 problem |
\hline
\end{tabular}
\caption{Bit Definitions for Machine State Register}
\end{table}

Programming Note

The only instructions that can alter MSR\textsubscript{SLE} are \texttt{mtsl}, \texttt{hrfid}, \texttt{rfid}, and \texttt{mtmsr}.
29:30  **Transaction State** (TS) [Category: Transactional Memory]

00 Non-transactional
01 Suspended
10 Transactional
11 Reserved

Changes to MSR[TS] that are caused by Transactional Memory instructions, and by invocation of the transaction’s failure handler, take effect immediately (even though these instructions and events are not context synchronizing).

31  **Transactional Memory Available** (TM) [Category: Transactional Memory]

0 The thread cannot execute any Transactional Memory instructions or access any Transactional Memory registers.
1 The thread can execute Transactional Memory instructions and access Transactional Memory registers unless the Transactional Memory facility has been made unavailable by some other register.

32:37 Reserved

38  **Vector Available** (VEC) [Category: Vector]

0 The thread cannot execute any vector instructions, including vector loads, stores, and moves.
1 The thread can execute vector instructions unless they have been made unavailable by some other register.

39 Reserved

40  **VSX Available** (VSX)

0 The thread cannot execute any VSX instructions, including VSX loads, stores, and moves.
1 The thread can execute VSX instructions unless they have been made unavailable by some other register.

**Programming Note**

An application binary interface defined to support Category: Vector-Scalar operations should also specify a requirement that MSR.FP and MSR.VEC be set to 1 whenever MSR.VSX is set to 1.

41:47 Reserved

48  **External Interrupt Enable** (EE)

0 External, Decrementer, Performance Monitor< S>, and Privileged Doorbell interrupts <S,PC> are disabled.
1 External, Decrementer, Performance Monitor< S>, and Privileged Doorbell interrupts <S,PC> are enabled.

This bit also affects whether Hypervisor Decrementer, Hypervisor Maintenance, and Directed Hypervisor Doorbell <S,PC> interrupts are enabled; see Section 6.5.12 on page 961, Section 6.5.19 on page 965, and Section 6.5.20 on page 966.

49  **Problem State** (PR)

0 The thread is in privileged state.
1 The thread is in problem state.

**Programming Note**

Any instruction that sets MSR.PR to 1 also sets MSREE, MSRIR, and MSRDR to 1.

50  **Floating-Point Available** (FP) [Category: Floating-Point]

0 The thread cannot execute any floating-point instructions, including floating-point loads, stores, and moves.
1 The thread can execute floating-point instructions unless they have been made unavailable by some other register.

**Machine Check Interrupt Enable** (ME)

0 Machine Check interrupts are disabled.
1 Machine Check interrupts are enabled.

This bit is a hypervisor resource; see Chapter 2., "Logical Partitioning (LPAR) and Thread Control", on page 843.

**Programming Note**

The only instructions that can alter MSR_ME are *rfid* and *hrfid*.

52  **Floating-Point Exception Mode 0** (FE0) [Category: Floating-Point]

See below.

53  **Single-Step Trace Enable** (SE) [Category: Trace]

0 The thread executes instructions normally.
1 The thread generates a Single-Step type Trace interrupt after successfully completing the execution of the next instruction, unless that instruction is a Power-Saving Mode instruction, *hrfid*, *rfid* or a Power-Saving Mode instruction, all of which are never traced. Successful completion means that the instruction caused no other interrupt and, if the processor is in the Transactional state <TM>, is not one of the instructions that is forbidden in Transactional state (e.g., *dcbf*, see Section 5.3.1 of Book II).
54  **Branch Trace Enable (BE)**
[Category: Trace]

0  The thread executes branch instructions normally.
1  The thread generates a Branch type Trace interrupt after completing the execution of a branch instruction, whether or not the branch is taken.

Branch tracing need not be supported on all implementations that support the Trace category. If the function is not implemented, this bit is treated as reserved.

55  **Floating-Point Exception Mode 1 (FE1)**
[Category: Floating-Point]

See below.

56:57  Reserved

58  **Instruction Relocate (IR)**

0  Instruction address translation is disabled.
1  Instruction address translation is enabled.

---

**Programming Note**

See the Programming Note in the definition of MSRPR.

59  **Data Relocate (DR)**

0  Data address translation is disabled. Effective Address Overflow (EAO) (see Book I) does not occur.
1  Data address translation is enabled. EAO causes a Data Storage interrupt.

---

**Programming Note**

See the Programming Note in the definition of MSRPR.

60  Reserved

61  **Performance Monitor Mark (PMM)**
[Category: Server]

---

**Programming Note**

See the Programming Note in the definition of MSRPR.

---

62  **Recoverable Interrupt (RI)**

0  Interrupt is not recoverable.
1  Interrupt is recoverable.

Additional information about the use of this bit is given in Sections 6.4.3, “Interrupt Processing” on page 947, 6.5.1, “System Reset Interrupt” on page 952, and 6.5.2, “Machine Check Interrupt” on page 953.

63  **Little-Endian Mode (LE)**
In the thread are in Big-Endian mode when MSR\_SLE=0. When MSR\_SLE=1, instruction storage accesses are in Big-Endian mode and data storage accesses are in Little-Endian mode.

Instruction and data storage accesses for the thread are in Little-Endian mode when MSR\_SLE=0. When MSR\_SLE=1, instruction storage accesses are in Little-Endian mode and data storage accesses are in Big-Endian mode.

Floating-Point Exception Mode bits FE0 and FE1 are interpreted as shown below. For further details see Book I.

<table>
<thead>
<tr>
<th>FE0</th>
<th>FE1</th>
<th>Mode</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>Ignore Exceptions</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>Imprecise Nonrecoverable</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>Imprecise Recoverable</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>Precise</td>
</tr>
</tbody>
</table>

The Floating-Point Exception Mode bits FE0 and FE1 are interpreted as shown below. For further details see Book I.

Table 2 shows all the Transaction State transitions that can be requested by rfebb, rfid, hrfid, and mtmsrd. The table covers behavior when TM is enabled by the PCR. For causes of the TM Bad Thing exception when TM is disabled by the PCR, see Section 6.5.9. In the table, the contents of MSR\_TS and MSR\_TM are abbreviated in the form AB, where A represents MSR\_TS (N, T or S) and B represents MSR\_TM (0 or 1). “x” in the “B” position means that the entry covers both MSR\_TM values, with the same value applying in all columns of a given row for a given instance of the transition. (E.g., the first row means that the transition from N0 to N0 is allowed and results in N0, and that the transition from N0 to N1 is allowed and results in N1.) “Input MSR\_TS\_SRTM” in the second column refers to the MSR\_TS and MSR\_TM values supplied by BESCR for rfebb (just the TS value), SRR1 for rfid, HSRR1 for hrfid, or register RS for mtmsrd.

3.2.2 State Transitions Associated with the Transactional Memory Facility [Category: Transactional Memory]

Updates to MSR\_TS and MSR\_TM caused by rfebb, rfid, hrfid, or mtmsrd occur as described in Table 2. The value written, and whether or not the instruction causes an interrupt, are dependent on the current values of MSR\_TS and MSR\_TM, and the values being written to these fields. When the setting of MSR\_TS causes an illegal state transition, a TM Bad Thing type Program interrupt is generated.
### Table 2: Transaction state transitions that can be requested by *rfebb*, *rfid*, *hrfid*, and *mtmsrd*.

</tbody>
</table>

**Notes:**
1. Generate TM Bad Thing type Program interrupt. “All others” includes all attempts to set MSR<sub>TS</sub> to 0b11 (reserved value).
2. Instruction completes, change to MSR<sub>TM</sub> suppressed, except when attempted by *rfebb*, in which case the result is a TM Bad Thing type Program interrupt.

Table 2: Transaction state transitions that can be requested by *rfebb*, *rfid*, *hrfid*, and *mtmsrd*.
For hrfid, and mtmsrd, the attempted transition from S0 to N0 is suppressed in order that interrupt handlers that are “unaware” of transactional memory, and load an MSR value that has not been updated to take account of transactional memory, will continue to work correctly. (If the interrupt occurs when a transaction is running or suspended, the interrupt will set MSR(TS + TM) to S0. If the interrupt handler attempts to load an MSR value that has not been updated to take account of transactional memory, that MSR value will have TS + TM = N0. It is desirable that the interrupt handler remain in state S0, so that it can return normally to the interrupted transaction.)

The problem solved by suppressing this transition does not apply to rfebb, so for rfebb an attempt to transition from S0 to N0 is not suppressed, and instead causes a TM Bad Thing type Program interrupt.
3.3 Branch Facility Instructions

3.3.1 System Linkage Instructions

These instructions provide the means by which a program can call upon the system to perform a service, and by which the system can return from performing a service or from processing an interrupt.

<table>
<thead>
<tr>
<th>System Call</th>
<th>SC-form</th>
</tr>
</thead>
<tbody>
<tr>
<td>sc</td>
<td>LEV</td>
</tr>
</tbody>
</table>

The System Call instruction is described in Book I, but only at the level required by an application programmer. A complete description of this instruction appears below.

The effective address of the instruction following the System Call instruction is placed into SRR0. Bits 0:32, 37:41, and 48:63 of the MSR are placed into the corresponding bits of SRR1, and bits 33:36 and 42:47 of SRR1 are set to zero.

Then a System Call interrupt is generated. The interrupt causes the MSR to be set as described in Section 6.5, “Interrupt Definitions” on page 950. The setting of the MSR is affected by the contents of the LEV field. LEV values greater than 1 are reserved. Bits 0:5 of the LEV field (instruction bits 20:25) are treated as a reserved field.

The interrupt causes the next instruction to be fetched from effective address 0x0000_0000_0000_0C00.

This instruction is context synchronizing.

**Special Registers Altered:**
- SRR0
- SRR1
- MSR

**Programming Note**

sc serves as both a basic and an extended mnemonic. The Assembler will recognize an sc mnemonic with one operand as the basic form, and an sc mnemonic with no operand as the extended form. In the extended form the LEV operand is omitted and assumed to be 0.

If LEV=1 the hypervisor is invoked. This is the only way that executing an instruction can cause hypervisor state to be entered.

Because this instruction is not privileged, it is possible for application software to invoke the hypervisor. However, such invocation should be considered a programming error.
**Return From Interrupt Doubleword**

**XL-form**

```
rfid
```

<table>
<thead>
<tr>
<th>0</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>21</th>
<th>18</th>
<th>31</th>
</tr>
</thead>
<tbody>
<tr>
<td>19</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\[
\begin{align*}
\text{MSR}_{51} & \leftarrow (\text{MSR}_3 \& \text{SRR1}_{51}) \mid (\neg\text{MSR}_3 \& \text{MSR}_{51}) \\
\text{MSR}_3 & \leftarrow \text{MSR}_3 \& \text{SRR1}_3 \\
\text{if} \ (\text{MSR}_{29:31} \neq 0b010 \ | \ \text{SRR1}_{29:31} \neq 0b000) \ \text{then} \\
\text{MSR}_{29:31} & \leftarrow \text{SRR1}_{29:31} \\
\text{MSR}_{48} & \leftarrow \text{SRR1}_{48} \mid \text{SRR1}_{49} \\
\text{MSR}_{58} & \leftarrow \text{SRR1}_{58} \mid \text{SRR1}_{49} \\
\text{MSR}_{59} & \leftarrow \text{SRR1}_{59} \mid \text{SRR1}_{49} \\
\text{MSR}_{0:2} & 4:28 \ 32 \ 37:41 \ 49:50 \ 52:57 \ 60:63 \leftarrow \text{SRR1}_{0:2} \ 4:28 \ 32 \ 37:41 \ 49:50 \ 52:57 \ 60:63 \\
\text{NIA} & \leftarrow \text{SRR0}_{0:61} \ | \ 0b00 \\
\end{align*}
\]

If MSR\(_3\)=1 then bits 3 and 51 of SRR1 are placed into the corresponding bits of the MSR. If bits 29 through 31 of the MSR are not equal to 0b010 or bits 29 through 31 of SRR1 are not equal to 0b000, then the value of bits 29 through 31 of SRR1 is placed into bits 29 through 31 of the MSR. The result of ORing bits 48 and 49 of SRR1 is placed into MSR\(_{48}\). The result of ORing bits 58 and 49 of SRR1 is placed into MSR\(_{58}\). The result of ORing bits 59 and 49 of SRR1 is placed into MSR\(_{59}\). Bits 0:2, 4:28, 32, 37:41, 49:50, 52:57, and 60:63 of SRR1 are placed into the corresponding bits of the MSR.

If the instruction attempts to cause an illegal transaction state transition (see Table 2, “Transaction state transitions that can be requested by rfebb, rfid, hrfid, and mtmsrd,” on page 861), or when TM is disabled by the PCR, a transition to Problem state with an active transaction, a TM Bad Thing type Program interrupt is generated (unless a higher-priority exception is pending). If this interrupt is generated, the value placed into SRR0 by the interrupt processing mechanism (see Section 6.4.3) is the address of the rfid instruction. Otherwise, if the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address SRR0\(_{61}\) || 0b00 (when SF=1 in the new MSR value) or SRR0\(_{32:61}\) || 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0 or HSRR0 by the interrupt processing mechanism (see Section 6.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is privileged and context synchronizing.

**Special Registers Altered:**

\[
\begin{align*}
\text{MSR} \\
\end{align*}
\]

---

**Programming Note**

If this instruction sets MSR\(_{PR}\) to 1, it also sets MSR\(_{EE}\), MSR\(_{IR}\), and MSR\(_{DR}\) to 1.
Hypervisor Return From Interrupt
Doubleword XL-form

hrfid

\[
\text{Table 3.1: Register Usage for HR RFID}
\]

<table>
<thead>
<tr>
<th>MSR</th>
<th>HSRR1</th>
</tr>
</thead>
<tbody>
<tr>
<td>274</td>
<td>31</td>
</tr>
</tbody>
</table>

\[
\text{Table 2: Transaction State Transitions that can be requested by \textbf{rfbb}, \textbf{rfid}, \textbf{hrfid}, and \textbf{mtmsrd.}}
\]

If bits 29 through 31 of the MSR are not equal to 0b010 or bits 29 through 31 of HSRR1 are not equal to 0b000, then the value of bits 29 through 31 of HSRR1 is placed into bits 29 through 31 of the MSR. The result of ORing bits 48 and 49 of HSRR1 is placed into MSR48. The result of ORing bits 58 and 49 of HSRR1 is placed into MSR58. The result of ORing bits 59 and 49 of HSRR1 is placed into MSR59. Bits 0:28, 32, 37:41, 49:57, and 60:63 of HSRR1 are placed into the corresponding bits of the MSR.

If the instruction attempts to cause an illegal transaction state transition (see Table 2, “Transaction state transitions that can be requested by rfebb, rfid, hrfid, and mtmsrd,” on page 861), or when TM is disabled by the PCR, a transition to Problem state with an active transaction, a TM Bad Thing type Program interrupt is generated (unless a higher-priority exception is pending). If this interrupt is generated, the value placed into SRR0 by the interrupt processing mechanism (see Section 6.4.3) is the address of the \textbf{hrfid} instruction.

Otherwise, if the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address HSRR0:061 || 0b00 (when SF=1 in the new MSR value) or 320 || HSRR0:32:61 || 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0 or HSRR0 by the interrupt processing mechanism (see Section 6.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is hypervisor privileged and context synchronizing.

Special Registers Altered:

- MSR

\[
\text{Programming Note}
\]

If this instruction sets MSR\text{PR} to 1, it also sets MSR\text{EE}, MSR\text{IR}, and MSR\text{DR} to 1.
3.3.2 Power-Saving Mode Instructions

The Power-Saving Mode instructions provide a means by which the hypervisor can put the thread into power-saving mode. When the thread is in power-saving mode it does not execute instructions, and it may consume less power than it would consume when it is not in power-saving mode.

There are four levels of power-savings, called doze, nap, sleep, and rvwinkle. For each level in this list, the power consumed is less than or equal to the power consumed in the preceding level, and the time required for the thread to exit from the level and for software then to resume normal operation is greater than or equal to the corresponding time for the preceding level. Doze power-saving level requires a minimum amount of such time, while the other levels may require more time. Resources other than those listed in the instruction descriptions that are maintained in each level other than doze, and the actions required by the hypervisor in order for software to resume normal operation after the thread exits from power-saving mode, are implementation-specific.

Read-only resources (including the HILE bit) are maintained in all power-saving levels. Descriptions of resource state loss in the Power-Saving Mode instruction descriptions do not apply to read-only resources.

---

**Programming Note**

The hypervisor determines which power-saving level to enter based on how responsive the system needs to be. If the hypervisor decides that some loss of state is acceptable, it can use the nap instruction rather than the doze instruction, and when the thread exits from power-saving mode the hypervisor can quickly determine whether any resources need to be restored.
The thread is placed into doze power-saving level.

When the thread is in doze power-saving level, the state of all thread resources is maintained as if the thread was not in power-saving mode.

When the interrupt that causes exit from doze power-saving level occurs, resource state is as described in the preceding paragraph, except that if the exception that caused the exit is a System Reset, Machine Check, or Hypervisor Maintenance exception, resource state that would be lost if the exception occurred when the thread was not in power-saving mode may be lost.

An attempt to execute this instruction in Suspended state will result in a TM Bad Thing type of Program interrupt. <TM>

This instruction is hypervisor privileged and context synchronizing.

Special Registers Altered:
None

Programming Note
If the state of the Decrementer were not maintained and updated as if the thread was not in power-saving mode, Decrementer exceptions would not reliably cause exit from nap power-saving level even if Decrementer exceptions were enabled to cause exit.
### Sleep

**XL-form**

```
sleep

19  ///  ///  ///  466  /
0  6  11  16  21  31
```

The thread is placed into sleep power-saving level.

When the thread is in sleep power-saving level, the state of all resources may be lost except for the HRMOR.

When the interrupt that causes exit from sleep power-saving level occurs, resource state is as described in the preceding paragraph, except that if the exception that caused the exit is a System Reset, Machine Check, or Hypervisor Maintenance exception, resource state that would be lost if the exception occurred when the thread was not in power-saving mode may be lost.

An attempt to execute this instruction in Suspended state will result in a TM Bad Thing type of Program interrupt. <TM>

This instruction is hypervisor privileged and context synchronizing.

**Special Registers Altered:**

None

**Programming Note**

If the state of the Decrementer is not maintained and updated, in sleep or rvwinkle power-saving level, as if the thread was not in power-saving mode, Decrementer exceptions will not reliably cause exit from power-saving mode even if Decrementer exceptions are enabled to cause exit.

**Note**

See the Notes that appear in the *rvwinkle* instruction description.

### Rip Van Winkle

**XL-form**

```
rwinkle

19  ///  ///  ///  498  /
0  6  11  16  21  31
```

The thread is placed into rvwinkle power-saving level.

When the thread is in rvwinkle power-saving level, the state of all resources may be lost except for the HRMOR.

When the interrupt that causes exit from rvwinkle power-saving level occurs, resource state is as described in the preceding paragraph, except that if the exception that caused the exit is a System Reset, Machine Check, or Hypervisor Maintenance exception, resource state that would be lost if the exception occurred when the thread was not in power-saving mode may be lost.

An attempt to execute this instruction in Suspended state will result in a TM Bad Thing type of Program interrupt. <TM>

This instruction is hypervisor privileged and context synchronizing.

**Special Registers Altered:**

None

**Programming Note**

In the short story by Washington Irving, Rip Van Winkle is a man who fell asleep on a green knoll and awoke twenty years later.

**Note**

See the Notes that appear in the *sleep* instruction description.
3.3.2.1 Entering and Exiting Power-Saving Mode

In order to enter power-saving mode, the hypervisor must use the instruction sequence shown below. Before executing this sequence, the hypervisor must ensure that LPCR\textsubscript{MER} contains the value 0, the LPCR\textsubscript{PECE} contains the desired value if doze or nap power-saving level is to be entered, MSR\textsubscript{SF}, MSR\textsubscript{HV}, and MSR\textsubscript{ME} contain the value 1, and all other bits of the MSR contain the value 0 except for MSR\textsubscript{RI}, which may contain either 0 or 1. Depending on the implementation and on the power-saving mode being entered, it may also be necessary for the hypervisor to save the state of certain resources before entering the sequence. The sequence must be exactly as shown, with no intervening instructions, except that any GPR may be used as Rx and as Ry, and any value may be used for “save_area” provided the resulting effective address is double-word aligned and corresponds to a valid real address.

```
std    Rx, save_area(Ry)    /* last store necessary to save state*/
ptesync  /* order load after*/
         /* last store */
ld     Rx, save_area(Ry)    /* reload from last location, */
         /* for synchronization */
loop:
cmp    Rx, Rx              /* create dependency */
bne   loop
nap/doze/sleep/rvwinkle  /* enter power-saving mode */
b $                   /* branch to self */
```

After the thread has entered power-saving mode as specified above, various exceptions may cause exit from power-saving mode. The exceptions include, System Reset, Machine Check, Decrementer, External, Hypervisor Maintenance, and implementation-specific exceptions. Upon exit from power-saving mode, if the exception was a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of SRR1 indicate the type of exception that caused exit from power-saving mode. See Section 6.5.1 for additional information.

**Programming Note**

The `ptesync` instruction (see Book III-S, Section 5.9.2) in the preceding sequence, in conjunction with the `ld` instruction and the loop, ensure that all storage accesses associated with instructions preceding the `ptesync` instruction, and all Reference, and Change bit updates associated with additional address translations that were performed, by the thread executing the `ptesync` instruction, before the `ptesync` instruction is executed, have been performed with respect to all threads and mechanisms, to the extent required by the associated Memory Coherence Required attributes, before the thread enters power-saving mode. The `b` instruction (branch to self) is not executed since the preceding Power-Saving Mode instruction puts the thread in a power-saving mode in which instructions are not executed. Even though it is not executed, requiring it to be present simplifies implementation and testing because it reduces the synchronization needed between execution of the instruction stream and entry into power-saving mode.

If the performance monitor is in use when the thread enters power-saving mode, the Performance Monitor data obtainable when the thread exits from power-saving mode may be incomplete or otherwise misleading.

**Programming Note**

Software is not required to set the RI bit to any particular value prior to entering power-saving mode because the setting of SRR1\textsubscript{62} upon exit from power-saving mode is independent of the value of the RI bit upon entry into power-saving mode.
3.4 Event-Based Branch Facility and Instruction

The Event-Based Branch facility is described in Chapter 7 of Book II, but only at the level required by the application program.

Event-based branches can only occur in problem state and when event-based branches has been enabled in the FSCR and HFSCR. If MSRPR=0, BESCRQE=1, and an event-based exception exists, the corresponding event-based branch does not occur until MSRPR=1, FSCR_EBB=1, and HFSCR_EBB=1.

If the rfebb instruction attempts to cause a transition to Transactional or Suspended state when PCRTM=1 or an illegal transaction state transition (see Section 3.2.2), a TM Bad Thing type Program interrupt is generated (unless a higher-priority exception is pending). If this interrupt is generated, the value placed into SRR0 by the interrupt processing mechanism is the address of the rfebb instruction.)
Chapter 4. Fixed-Point Facility

4.1 Fixed-Point Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Fixed-Point Facility that are not covered in Book I.

4.2 Special Purpose Registers

Special Purpose Registers (SPRs) are read and written using the `mfspr` (page 885) and `mtspr` (page 884) instructions. Most SPRs are defined in other chapters of this book; see the index to locate those definitions.

4.3 Fixed-Point Facility Registers

4.3.1 Processor Version Register

The Processor Version Register (PVR) is a 32-bit read-only register that contains a value identifying the version and revision level of the implementation. The contents of the PVR can be copied to a GPR by the `mfspr` instruction. Read access to the PVR is privileged; write access is not provided.

The PVR distinguishes between implementations that differ in attributes that may affect software. It contains two fields.

**Version**
A 16-bit number that identifies the version of the implementation. Different version numbers indicate major differences between implementations, such as which categories are supported.

**Revision**
A 16-bit number that distinguishes between implementations of the version. Different revision numbers indicate minor differences between implementations having the same version number, such as clock rate and Engineering Change level.

Version numbers are assigned by the Power ISA process. Revision numbers are assigned by an implementation-defined process.

4.3.2 Chip Information Register

The Chip Information Register (CIR) is a 32-bit read-only register that contains a value identifying the manufacturer and other characteristics of the chip on which the processor is implemented. The contents of the CIR can be copied to a GPR by the `mfspr` instruction. Read access to the CIR is privileged; write access is not provided.

**Bit Description**

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:35</td>
<td>Manufacturer ID (ID) A four-bit field that identifies the manufacturer of the chip.</td>
</tr>
<tr>
<td>36:63</td>
<td>Implementation-dependent.</td>
</tr>
</tbody>
</table>

Figure 9. Chip Information Register

4.3.3 Processor Identification Register

The Processor Identification Register (PIR) is a 32-bit register that contains a value that can be used to distinguish the thread from other threads in the system. The contents of the PIR can be copied to a GPR by the...
mfspr instruction. Read access to the PIR is privileged; write access is not provided.

Figure 10. Processor Identification Register

The means by which the PIR is initialized are implementation-dependent.

The PIR is a hypervisor resource; see Chapter 2.

4.3.4 Control Register

The Control Register (CTRL) is a 32-bit register as shown below.

<table>
<thead>
<tr>
<th>32</th>
<th>48</th>
<th>56</th>
<th>63</th>
</tr>
</thead>
<tbody>
<tr>
<td>///</td>
<td>TS</td>
<td>///</td>
<td>RUN</td>
</tr>
</tbody>
</table>

Figure 11. Control Register

The field definitions for the CTRL are shown below.

### Bit(s) Description

| 32:47 | Reserved |
| 48:55 | Thread State (TS) |
| 56:62 | Reserved |
| 63 | RUN |

**Description**

- **Thread State (TS)**
  - Problem State Access
  - Privileged accesses
    - Bits 0:7 of this field are read-only bits that indicate the state of CTRL_RUN for threads with privileged thread numbers 0 through 7, respectively; bits corresponding to privileged thread numbers higher than the maximum privileged thread number supported are set to 0s.
  - Hypervisor accesses
    - Bits 0:7 of this field are read-only bits that indicate the state of CTRL_RUN for threads with hypervisor thread numbers 0 through 7, respectively; bits corresponding to hypervisor thread numbers higher than the maximum hypervisor thread number supported are set to 0s.

- **RUN**
  - This bit controls an external I/O pin. This signal may be used for the following:
    - Driving the RUN Light on a system operator panel
    - Direct External exception routing
    - Performance Monitor Counter incrementing (See Chapter 9.)

The RUN bit can be used by the operating system to indicate when the thread is doing useful work.

Write access to the CTRL is privileged. Reads can be performed in privileged or problem state.

4.3.5 Program Priority Register

Privileged programs may set a wider range of program priorities in the PRI field of PPR and PPR32 than may be set by problem-state programs (see Chapter 3 of Book II). Problem-state programs may only set values in the range of 0b001 to 0b100 unless the Problem
State Priority Boost register (see Section 4.3.6) allows the value 0b101. Privileged programs may set values in the range of 0b001 to 0b110. Hypervisor software may also set 0b111. For all priorities except 0b101, if a program attempts to set a value that is not allowed for its privilege level, the PRI field remains unchanged. If a problem-state program attempts to set its priority value to 0b101 when this priority value is not allowed for problem state programs, the priority is set to 0b100. The values and their corresponding meanings are as follows.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>11:13</td>
<td>Program Priority (PRI)</td>
<td>001 very low, 010 low, 011 medium low, 100 medium, 101 medium high, 110 high, 111 very high</td>
</tr>
</tbody>
</table>

### 4.3.6 Problem State Priority Boost Register

The Problem State Priority Boost (PSPB) register is a 32-bit register that controls whether problem-state programs have access to program priority medium high. (See Section 3.1 of Book II.)

Figure 12. Problem-State Priority Boost Register

A problem state program is able to set the program priority to medium high only when the PSPB of the thread contains a non-zero value. The maximum value to which the PSPB can be set must be a power of 2 minus 1. Bits that are not required to represent this maximum value must return 0s when read regardless of what was written to them.

When the PSPB is set to a value less than its maximum value but greater than 0, its contents decrease monotonically at the same rate as the SPURR until its contents minus the amount it is to be decreased are 0 or less when a problem-state program is executing on the thread at a priority of medium high. When the contents of the PSPB minus the amount it is to be decreased are 0 or less, its contents are replaced by 0.

When the PSPB is set to its maximum value or 0, its contents do not change until it is set to a different value.

Whenever the priority of a thread is medium high and either of the following conditions exist, hardware changes the priority to medium:

- the PSPB counts down to 0, or
- PSPB=0 and the privilege state of the thread is changed to problem state (MSR_{PP}=1).

### 4.3.7 Relative Priority Register

The Relative Priority Register (RPR) is a 64-bit register that allows the hypervisor to control the relative priorities corresponding to each valid value of PPR_{PRI}.

<table>
<thead>
<tr>
<th>bits</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:1</td>
<td>Reserved</td>
</tr>
<tr>
<td>2:7</td>
<td>Relative priority of priority level n: Specifies the relative priority that corresponds to the priority corresponding to PPR_{PRI}=n, where a value of 0 indicates the lowest relative priority and a value of 0b111111 indicates the highest relative priority.</td>
</tr>
</tbody>
</table>

Programming Note

The hypervisor must ensure that the values of the RP_n fields increase monotonically for each n and are of different enough magnitudes to ensure that each priority level provides a meaningful difference in priority.

### 4.3.8 Software-use SPRs

Software-use SPRs are 64-bit registers provided for use by software.

<table>
<thead>
<tr>
<th>SPRG0</th>
<th>SPRG1</th>
<th>SPRG2</th>
<th>SPRG3</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>63</td>
<td>0</td>
<td>63</td>
</tr>
</tbody>
</table>

Figure 14. Software-use SPRs

SPRG0, SPRG1, and SPRG2 are privileged registers. SPRG3 is a privileged register except that the contents may be copied to a GPR in Problem state when accessed using the mispr instruction.
HSPRG0 and HSPRG1 are 64-bit registers provided for use by hypervisor programs.

Neither the contents of the SPRGs, nor accessing them using `mtspr` or `mfspr`, has a side effect on the operation of the thread. One or more of the registers is likely to be needed by non-hypervisor interrupt handler programs (e.g., as scratch registers and/or pointers to per thread save areas).

Operating systems must ensure that no sensitive data are left in SPRG3 when a problem state program is dispatched, and operating systems for secure systems must ensure that SPRG3 cannot be used to implement a “covert channel” between problem state programs. These requirements can be satisfied by clearing SPRG3 before passing control to a program that will run in problem state.

**Programming Note**

Neither the contents of the HSPRGs, nor accessing them using `mtspr` or `mfspr`, has a side effect on the operation of the thread. One or more of the registers is likely to be needed by hypervisor interrupt handler programs (e.g., as scratch registers and/or pointers to per thread save areas).
4.4 Fixed-Point Facility Instructions

4.4.1 Fixed-Point Load and Store Caching Inhibited Instructions

The storage accesses caused by the instructions described in this section are performed as though the specified storage location is Caching Inhibited and Guarded. The instructions can be executed only in hypervisor state. Software must ensure that the specified storage location is not in the caches. If the specified storage location is in a cache, the results are undefined.

The Fixed-Point Load and Store Caching Inhibited instructions must be executed only when MSR_D=0. The storage location specified by the instructions must not be in storage specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded. If either of these conditions is violated, the result is a data storage interrupt.

---

**Programming Note**

The instructions described in this section can be used to permit a control register on an I/O device to be accessed without permitting the corresponding storage location to be copied into the caches.

See also, in Book I, the introductions to Section 3.3.1, “Fixed-Point Storage Access Instructions”, Section 3.3.2, “Fixed-Point Load Instructions”, and Section 3.3.3, “Fixed-Point Store Instructions”.

4.4.2 OR Instruction

(or Rx,Rx,Rx) can be used to set PPRPRI (see Section 4.3.5) as shown in Figure 16. For all priorities except medium high, PPRPRI remains unchanged if the privilege state of the thread executing the instruction is lower than the privilege indicated in the figure. For priority medium high, PPRPRI is set to medium if the thread executing the instruction is in problem state and medium high priority is not allowed for problem state programs. (The encodings available to problem-state programs, as well as encodings for additional shared resource hints not shown here, are described in Chapter 3 of Book II.)

</tr>
</tbody>
</table>

\(^1\)This value is privileged unless the Problem State Priority Boost register allows the priority value 0b101 (See Section 4.3.6.)
4.4.3 Transactional Memory Instructions [Category: Transactional Memory]

Privileged software that makes the Transactional Memory Facility available to applications takes on the responsibility of managing the facility's resources and the application's transactional state during interrupt handling, service calls, task switches, and its own use of TM. In addition to the existing instructions like rfid and problem state TM instructions that play a role in this management, **treclaim** and **trechkpt.** may be used, as described below. See Section 3.2.2 for additional information about managing the TM facility and associated state transitions.

**Transaction Reclaim X-form**

treclaim. RA

<table>
<thead>
<tr>
<th>CR0</th>
<th>RA</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>31</th>
<th>28</th>
<th>25</th>
<th>22</th>
<th>19</th>
<th>16</th>
<th>13</th>
<th>10</th>
<th>7</th>
<th>4</th>
<th>1</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

if MSR$_{TS}$ = 0b10 | MSR$_{PS}$ = 0b01 then
  if RA = 0 then cause <- 0x00000001
  else cause <- GPR(RA)$_{56:63}$ || 0x000001
  if TEXASR$_{PS}$ = 0 then
    Discard transactional footprint
    TMRecordFailure(cause)
    Revert checkpointed registers to pre-transactional values
    Discard all resources related to current transaction
  MSR$_{PS}$ <- 0b00  #Non-transactional

The **treclaim.** instruction frees the transactional facility for use by a new transaction. It sets condition register field 0 to 0 || MSR$_{TS}$ || 0. If the transactional facility is in the Transactional state or Suspended state, failure recording is performed as defined in Section 5.3.2 of Book II. If RA is 0, the failure cause is set to 0x00000001, otherwise it is set to GPR(RA)$_{56:63}$ || 0x000001. The checkpointed registers are reverted to their pre-transactional values, and all resources related to the current transaction are discarded, including the transactional footprint (if it wasn’t already discarded for a pending failure).

The transaction state is set to Non-transactional.

If an attempt is made to execute **treclaim.** in Non-transactional state, a TM Bad Thing type Program interrupt will be generated.

This instruction is privileged.
**Transaction Recheckpoint X-form**

**trechkpt.**

<table>
<thead>
<tr>
<th>31</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>21</th>
<th>1006</th>
<th>1</th>
</tr>
</thead>
</table>

CR0 ← 0 || MSR_{TS} || 0

MSR_{TS} ← 0b01

TDOOMED ← 1

checkpoint area ← {checkpointed registers}

The **trechkpt.** instruction copies the current (pre-transacational, saved and restored by the operating system) register state to the checkpoint area. It sets condition register field 0 to 0 || MSR_{TS} || 0. The current values of the checkpointed registers are loaded into the checkpoint area. TDOOMED is set to 0b1.

The transaction state is set to Suspended.

If an attempt is made to execute this instruction in Transactional or Suspended state or when TEXAS-RFS=0, a TM Bad Thing type Program interrupt will be generated.

This instruction is privileged.

**Special Registers Altered**

CR0 TS

### 4.4.4 Move To/From System Register Instructions

The Move To Special Purpose Register and Move From Special Purpose Register instructions are described in Book I, but only at the level available to an application programmer. For example, no mention is made there of registers that can be accessed only in privileged state. The descriptions of these instructions given below extend the descriptions given in Book I, but do not list Special Purpose Registers that are implementation-dependent. In the descriptions of these instructions given below, the “defined” SPR numbers are the SPR numbers shown in the figure for the instruction and the implementation-specific SPR numbers that are implemented, and similarly for “defined” registers.

SPR numbers that are not shown in Figure 17 and are in the ranges shown below are reserved for implementation-specific uses.

- 848 - 863
- 880 - 895
- 976 - 991
- 1008 - 1023

Implementation-specific registers must be privileged.

SPR numbers for implementation-specific SPRs should be registered in advance with the Power ISA architects.

**Extended mnemonics**

Extended mnemonics are provided for the **mtspr** and **mfspr** instructions so that they can be coded with the SPR name as part of the mnemonic rather than as a numeric operand. See Appendix A, “Assembler Extended Mnemonics” on page 1015.

1. This register is not defined for this instruction.
2. Note that the order of the two 5-bit halves of the SPR number is reversed.
3. This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2).
4. This register cannot be directly written. Instead, bits in the register corresponding to 0 bits in (RS) can be cleared using `mtspr SPR,RS`.
5. The value specified in register RS may be masked by the contents of the [U]AMOR before being placed into the AMR; see the `mtspr` instruction description.
6. The value specified in register RS may be ANDed with the contents of the AMOR before being placed into the UAMOR; see the `mtspr` instruction description.
7. MMCR0PMCC controls the availability of this SPR, and its contents depend on the privilege state in which it is accessed. See Section 9.4.4 for details.
8. The value specified in Register RS may be masked by the contents of the AMOR before being placed into the IAMR; see the `mtspr` instruction description.
9. Accesses to these SPRs are noops; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I.

SPR numbers 777-778, 783, 793-794, and 799 are reserved for the Performance Monitor. All other SPR numbers that are not shown above are not implementation-specific are reserved.

n ← spr5..9 || spr0..4

switch (n)

case(13): if MSRHV PR = 0b10 then
SPR(13) ← (RS)
else
if MSRHV PR = 0b00 then
SPR(13) ← ((RS) & AMOR) | ((SPR(13)) & ¬AMOR)
else
SPR(13) ← (RS) & UAM OR | ((SPR(13)) & ¬UAMOR)

case(29,61): if MSRHV PR = 0b10 then
SPR(n) ← (RS)
else
SPR(n) ← ((RS) & AMOR) | ((SPR(n)) & ¬AMOR)

case (157): if MSRHV PR = 0b10 then
SPR(157) ← (RS)
else
SPR(157) ← (RS) & AMOR

case (336): SPR(336) ← (SPR(336)) & (RS)

case (808, 809, 810, 811):
default: if length(SPR(n)) = 64 then
SPR(n) ← (RS)
else
SPR(n) ← (RS)32:63

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 17. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of register RS are placed into the designated Special Purpose Register, except as described in the next four paragraphs. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RS are placed into the SPR.

When the designated SPR is the Authority Mask Register (AMR), (using SPR 13 or SPR 29), or the designated SPR is the Instruction Authority Mask Register (IAMR), and MSRPR=0b00, the contents of bit positions of register RS corresponding to 1 bits in the Authority Mask Override Register (AMOR) are placed into the corresponding bits of the AMR; the other AMR bits are not modified.

When the designated SPR is the AMR, using SPR 13, and MSRPR=1, the contents of bit positions of register RS corresponding to 1 bits in the User Authority Mask Override Register (UAMOR) are placed into the corresponding bits of the AMR; the other AMR bits are not modified.

When the designated SPR is the UAMOR and MSRPR=0b00, the contents of register RS are ANDed with the contents of the AMOR and the result is placed into the UAMOR.

When the designated SPR is the Hypervisor Maintenance Exception Register (HMER), the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

For this instruction, SPRs TBL and TBU are treated as separate 32-bit registers; setting one leaves the other unaltered.

spr0=1 if and only if writing the register is privileged. Execution of this instruction specifying an SPR number with spr0=1 causes a Privileged Instruction type Program interrupt when MSRPR=1 and, if the SPR is a hypervisor resource (see Figure 17), when MSRHV PR=0b00.

Execution of this instruction specifying an SPR number that is not defined for the implementation, including SPR numbers that are shown in Figure 17 but are in a category that is not supported by the implementation, causes one of the following.

<table>
<thead>
<tr>
<th>if spr0=0:</th>
</tr>
</thead>
<tbody>
<tr>
<td>- if MSRPR=1: Hypervisor Emulation Assistance interrupt</td>
</tr>
<tr>
<td>- if MSRPR=0: Hypervisor Emulation Assistance interrupt for SPR 0 and no operation (i.e. the instruction is treated as a no-op) for all other SPRs</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>if spr0=1:</th>
</tr>
</thead>
<tbody>
<tr>
<td>- if MSRPR=1: Privileged Instruction type Program interrupt</td>
</tr>
<tr>
<td>- if MSRPR=0: no operation (i.e. the instruction is treated as a no-op)</td>
</tr>
</tbody>
</table>

If an attempt is made to execute mtspr specifying a TM SPR in other than Non-transactional state, a TM Bad Thing type Program interrupt is generated.

**Special Registers Altered:**
See Figure 17

**Programming Note**

For a discussion of software synchronization requirements when altering certain Special Purpose Registers, see Chapter 12, “Synchronization Requirements for Context Alterations” on page 1009.
Chapter 4. Fixed-Point Facility

Move From Special Purpose Register

XFX-form

mfspr RT,SPR

<table>
<thead>
<tr>
<th>31</th>
<th>8</th>
<th>11 spr</th>
<th>21</th>
<th>339</th>
</tr>
</thead>
</table>

n ← spr_{5:9} | spr_{0:4}

switch (n)

  case(129):
    if (MSRH_{PR} = 0b10)&(TFIARHV_{PR}=MSRH_{PR}) |
    ((MSRH_{PR} = 0b00) & (TFIARHV_{PR} = 0b01)) then
      RT ← SPR(n)
    else
      RT ← 0

  case(808, 809, 810, 811):

  default:
    if length(SPR(n)) = 64 then
      RT ← SPR(n)
    else
      RT ← 320 || SPR(n)

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 17. If the designated Special Purpose Register is the TFIAR and TFIAR indicates the failure was recorded in a state more privileged than the current state, register RT is set to zero. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of the designated Special Purpose Register are placed into register RT. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RT receive the contents of the Special Purpose Register and the high-order 32 bits of RT are set to zero.

### Programming Note

Note that when a problem state transaction’s failure is recorded in hypervisor state and there is a subsequent need for a context switch in privileged, non-hypervisor state, an attempt to save TFIAR will result in zeros being saved. This is harmless because if the original application ever tries to read the TFIAR, it would read zeros anyway, since the failure took place in hypervisor state.

- **if spr_0=0:**
  - if MSR_{PR}=1: Hypervisor Emulation Assistance interrupt
  - if MSR_{PR}=0: Hypervisor Emulation Assistance interrupt for SPRs 0, 4, 5, and 6 and no operation (i.e. the instruction is treated as a no-op) for all other SPRs

- **if spr_0=1:**
  - if MSR_{PR}=1: Privileged Instruction type Program interrupt
  - if MSR_{PR}=0: no operation (i.e. the instruction is treated as a no-op)

### Special Registers Altered:

None

**Note**

See the Notes that appear with mtspr.

- **spr_0=1** if and only if reading the register is privileged.

  Execution of this instruction specifying an SPR number with spr_0=1 causes a Privileged Instruction type Program interrupt when MSR_{PR}=1 and, if the SPR is a hypervisor resource (see Figure 17), when MSR_{HY_{PR}}=0b00.

  Execution of this instruction specifying an SPR number that is not defined for the implementation, including SPR numbers that are shown in Figure 17 but are in a category that is not supported by the implementation, causes one of the following.

---

Version 2.07
Move To Machine State Register X-form

mtmsr   RS, L

if L = 0 then
    MSR48  ← (RS)48 | (RS)49
    MSR58  ← (RS)58 | (RS)49
    MSR59  ← (RS)59 | (RS)49
else
    MSR48 62  ← (RS)48 62

The MSR is set based on the contents of register RS and of the L field.

L=0:

The result of ORing bits 48 and 49 of register RS is placed into MSR48. The result of ORing bits 58 and 49 of register RS is placed into MSR58. The result of ORing bits 59 and 49 of register RS is placed into MSR59. Bits 32:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

L=1:

Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

This instruction is privileged.

If L=0 this instruction is context synchronizing. If L=1 this instruction is execution synchronizing; in addition, the alterations of the EE and RI bits take effect as soon as the instruction completes.

Special Registers Altered:

MSR

Except in the mtmsr instruction description in this section, references to "mtmsr" in this document imply either L value unless otherwise stated or obvious from context (e.g., a reference to an mtmsr instruction that modifies an MSR bit other than the EE or RI bit implies L=0).

Programming Note

If this instruction sets MSRPR to 1, it also sets MSREE, MSRIR, and MSDDR to 1.

This instruction does not alter MSRME or MSREL.
(This instruction does not alter MSRHV because it does not alter any of the high-order 32 bits of the MSR.)

If the only MSR bits to be altered are MSREE, to obtain the best performance L=1 should be used.

Programming Note

If MSREE=0 and an External, Decrementer, or Performance Monitor exception is pending, executing an mtmsrd instruction that sets MSREE to 1 will cause the interrupt to occur before the next instruction is executed, if no higher priority exception exists (see Section 6.8, "Interrupt Priorities" on page 970). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 12.

Programming Note

mtmsr serves as both a basic and an extended mnemonic. The Assembler will recognize an mtmsr mnemonic with two operands as the basic form, and an mtmsr mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

Programming Note

There is no need for an analogous version of the mfmsr instruction, because the existing instruction copies the entire contents of the MSR to the selected GPR.
Move To Machine State Register
Doubleword X-form

mtmsrd RS,L

<table>
<thead>
<tr>
<th>31</th>
<th>RS</th>
<th>///</th>
<th>L</th>
<th>///</th>
<th>178</th>
<th>/</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>11</td>
<td>15</td>
<td>21</td>
<td>28</td>
<td>32</td>
<td>47</td>
</tr>
</tbody>
</table>

if L = 0 then

if (MSR29:31 ← 0b010 | RS29:31 ← 0b000) then
MSR29:31 ← RS29:31
MSR48 ← (RS)48 | (RS)49
MSR58 ← (RS)58 | (RS)49
MSR59 ← (RS)59 | (RS)49
else
MSR48 62 ← (RS)48 62

The MSR is set based on the contents of register RS and of the L field.

L=0: If bits 29 through 31 of the MSR are not equal to 0b010 or bits 29 through 31 of RS are not equal to 0b000, then the value of bits 29 through 31 of RS is placed into bits 29 through 31 of the MSR. The result of ORing bits 48 and 49 of register RS is placed into MSR48. The result of ORing bits 58 and 49 of register RS is placed into MSR58. The result of ORing bits 59 and 49 of register RS is placed into MSR59. Bits 0:2, 4:28, 32:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

L=1: Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

If the instruction attempts to cause an illegal transaction state transition (see Table 2, "Transaction state transitions that can be requested by rfebb, rfid, hrfd, and mtmsrd," on page 861), or when TM is disabled by the PCR, a transition to Problem state with an active transaction is generated (unless a higher-priority exception exists (see Section 6.8, "Interrupt Priorities" on page 970). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 12.

mtmsrd serves as both a basic and an extended mnemonic. The Assembler will recognize an mtmsrd mnemonic with two operands as the basic form, and an mtmsrd mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

Except in the mtmsrd instruction description in this section, references to ‘mtmsrd’ in this document imply either L value unless otherwise stated or obvious from context (e.g., a reference to an mtmsrd instruction that modifies an MSR bit other than the EE or RI bit implies L=0).

Programming Note
If this instruction sets MSRPR to 1, it also sets MSRLE, MSRME, and MSRD to 1.
This instruction does not alter MSREE, MSRIE, or MSRDR.
If the only MSR bits to be altered are MSREE, to obtain the best performance L=1 should be used.

Programming Note
If MSREE=0 and an External, Decrementer, or Performance Monitor exception is pending, executing an mtmsrd instruction that sets MSREE to 1 will cause the interrupt to occur before the next instruction is executed, if no higher priority exception exists (see Section 6.8, "Interrupt Priorities" on page 970). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 12.

Programming Note
mtmsrd serves as both a basic and an extended mnemonic. The Assembler will recognize an mtmsrd mnemonic with two operands as the basic form, and an mtmsrd mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

This instruction is privileged.

**Special Registers Altered:**

None
Chapter 5. Storage Control

5.1 Overview

A program references storage using the effective address computed by the hardware when it executes a Load, Store, Branch, or Cache Management instruction, or when it fetches the next sequential instruction. The effective address is translated to a real address according to procedures described in Section 5.7.3, in Section 5.7.5 and in the following sections. The real address is what is presented to the storage subsystem.

For a complete discussion of storage addressing and effective address calculation, see Section 1.10 of Book I.

5.2 Storage Exceptions

A storage exception results when the sequential execution model requires that a storage access be performed but the access is not permitted (e.g., is not permitted by the storage protection mechanism), the access cannot be performed because the effective address cannot be translated to a real address, or the access matches some tracking mechanism criteria (e.g., Data Address Watchpoint).

In certain cases a storage exception may result in the “restart” of (re-execution of at least part of) a Load or Store instruction. See Section 2.1 of Book II, and Section 6.6 in this Book.

5.3 Instruction Fetch

Instructions are fetched under control of MSR\textsubscript{IR}.

\textbf{MSR\textsubscript{IR}=0}

The effective address of the instruction is interpreted as described in Section 5.7.3.

\textbf{MSR\textsubscript{IR}=1}

The effective address of the instruction is translated by the Address Translation mechanism described beginning in Section 5.7.5.

5.3.1 Implicit Branch

Explicitly altering certain MSR bits (using \texttt{mtmsr[\textit{d}]}) or explicitly altering SLB entries, Page Table Entries, or certain System Registers (including the HRMOR, and possibly other implementation-dependent registers), may have the side effect of changing the addresses, effective or real, from which the current instruction stream is being fetched. This side effect is called an \textit{implicit branch}. For example, an \texttt{mtmsrd} instruction that changes the value of MSR\textsubscript{SF} may change the effective addresses from which the current instruction stream is being fetched. The MSR bits and System Registers (excluding implementation-dependent registers) for which alteration can cause an implicit branch are indicated as such in Chapter 12. “Synchronization Requirements for Context Alterations” on page 1009. Implicit branches are not supported by the Power ISA. If an implicit branch occurs, the results are boundedly undefined.

5.3.2 Address Wrapping Combined with Changing MSR Bit SF

If the current instruction is at effective address $2^{32} - 4$ and is an \texttt{mtmsrd} instruction that changes the contents of MSR\textsubscript{SF}, the effective address of the next sequential instruction is undefined.

\textbf{Programming Note}

In the case described in the preceding paragraph, if an interrupt occurs before the next sequential instruction is executed, the contents of SRR0, or HSRR0, as appropriate to the interrupt, are undefined.

5.4 Data Access

Data accesses are controlled by MSR\textsubscript{DR}.

\textbf{MSR\textsubscript{DR}=0}

The effective address of the data is interpreted as described in Section 5.7.3.
The effective address of the data is translated by the Address Translation mechanism described in Section 5.7.5.

5.5 Performing Operations Out-of-Order

An operation is said to be performed “in-order” if, at the time that it is performed, it is known to be required by the sequential execution model. An operation is said to be performed “out-of-order” if, at the time that it is performed, it is not known to be required by the sequential execution model.

Operations are performed out-of-order on the expectation that the results will be needed by an instruction that will be required by the sequential execution model. Whether the results are really needed is contingent on everything that might divert the control flow away from the instruction, such as Branch, Trap, System Call, and Return From Interrupt instructions, and interrupts, and on everything that might change the context in which the instruction is executed.

Typically, operations are performed out-of-order when resources are available that would otherwise be idle, so the operation incurs little or no cost. If subsequent events such as branches or interrupts indicate that the operation would not have been performed in the sequential execution model, any results of the operation are abandoned (except as described below).

In the remainder of this section, including its subsections, “Load instruction” includes the Cache Management and other instructions that are stated in the instruction descriptions to be “treated as a Load”, and similarly for “Store instruction”.

A data access that is performed out-of-order may correspond to an arbitrary Load or Store instruction (e.g., a Load or Store instruction that is not in the instruction stream being executed). Similarly, an instruction fetch that is performed out-of-order may be for an arbitrary instruction (e.g., the aligned word at an arbitrary location in instruction storage).

Most operations can be performed out-of-order, as long as the machine appears to follow the sequential execution model. Certain out-of-order operations are restricted, as follows.

- Stores
  Stores are not performed out-of-order (even if the Store instructions that caused them were executed out-of-order).

- Accessing Guarded Storage
  The restrictions for this case are given in Section 5.8.1.1.
5.7 Storage Addressing

Storage Control Overview
- Real address space size is $2^m$ bytes, $m \leq 60$; see Note 1.
- Real page size is $2^{12}$ bytes (4 KB).
- Effective address space size is $2^{64}$ bytes.
- An effective address is translated to a virtual address via the Segment Lookaside Buffer (SLB).
  - Virtual address space size is $2^n$ bytes, $65 \leq n \leq 78$; see Note 2.
  - Segment size is $2^s$ bytes, $s=28$ or $40$.
  - $2^{n-40} \leq$ number of virtual segments $\leq 2^{n-28}$; see Note 2.
  - Virtual page size is $2^p$ bytes, where $12 \leq p$, and $2^p$ is no larger than either the size of the biggest segment or the real address space; a size of 4 KB, 64 KB, and an implementation-dependent number of other sizes are supported; see Note 3. The Page Table specifies the virtual page size. The SLB specifies the base virtual page size, which is the smallest virtual page size that the segment can contain. The base virtual page size is $2^b$ bytes.
- Segments contain pages of a single size, a mixture of 4 KB and 64 KB pages, or a mixture of page sizes that include implementation-dependent page sizes.
- A virtual address is translated to a real address via the Page Table.

Notes:
1. The value of $m$ is implementation-dependent (subject to the maximum given above). When used to address storage, the high-order 60-$m$ bits of the “60-bit” real address must be zeros.
2. The value of $n$ is implementation-dependent (subject to the range given above). In references to 78-bit virtual addresses elsewhere in this Book, the high-order 78-$n$ bits of the “78-bit” virtual address are assumed to be zeros.
3. The supported values of $p$ for the larger virtual page sizes are implementation-dependent (subject to the limitations given above).

5.7.1 32-Bit Mode
The computation of the 64-bit effective address is independent of whether the thread is in 32-bit mode or 64-bit mode. In 32-bit mode (MSRSF=0), the high-order 32 bits of the 64-bit effective address are treated as zeros for the purpose of addressing storage. This applies to both data accesses and instruction fetches. It applies independent of whether address translation is enabled or disabled. This truncation of the effective address is the only respect in which storage accesses in 32-bit mode differ from those in 64-bit mode.

Programming Note
Treating the high-order 32 bits of the effective address as zeros effectively truncates the 64-bit effective address to a 32-bit effective address such as would have been generated on a 32-bit implementation of the Power ISA. Thus, for example, the ESID in 32-bit mode is the high-order four bits of this truncated effective address; the ESID thus lies in the range 0-15. When address translation is enabled, these four bits would select a Segment Register on a 32-bit implementation of the Power ISA. The SLB entries that translate these 16 ESIDs can be used to emulate these Segment Registers.

5.7.2 Virtualized Partition Memory (VPM) Mode
VPM mode enables the hypervisor to reassign all or part of a partition’s memory transparently so that the reassignment is not visible to the partition. When this is done, the partition’s memory is said to be “virtualized.” The VPM field in the LPCR enables VPM mode separately when address translation is enabled and when translation is disabled.

If the thread is not in hypervisor state, and either address translation is enabled and VPM1=1, or address translation is disabled and VPM0=1, conditions that would have caused a Data Storage or an Instruction Storage interrupt if the affected memory were not virtualized instead cause a Hypervisor Data Storage or a Hypervisor Instruction Storage interrupt respectively. Because the Hypervisor Data Storage and Hypervisor Instruction Storage interrupts always put the thread in hypervisor state, they permit the hypervisor to handle the condition if appropriate (e.g., to restore the contents of a page that was reassigned), and to reflect it to the operating system’s Data Storage or Instruction Storage interrupt handler otherwise.

When address translation is enabled, VPM mode has no effect on address translation. When address translation is disabled, addressing is controlled as specified in Section 5.7.3.

5.7.3 Real And Virtual Real Addressing Modes
When a storage access is an instruction fetch performed when instruction address translation is disabled, or if the access is a data access and data address translation is disabled, it is said to be per-
formed in "real addressing mode" if VPM0=0 and the thread is not in hypervisor state. If the thread is in hypervisor state, the access is said to be performed in "hypervisor real addressing mode" regardless of the value of VPM0. If the thread is not in hypervisor state and VPM0=1, the access is said to be performed in "virtual real addressing mode." Storage accesses in real, hypervisor real, and virtual real addressing modes are performed in a manner that depends on the contents of MSR_HV, VPM, VRMASD, HRMOR, RMLS, RMOR (see Chapter 2), bit 0 of the effective address (EA0), and the state of the Real Mode Storage Control Facility as described below. Bits 1:3 of the effective address are ignored.

MSR_HV=1

- If EA0=0, the Hypervisor Offset Real Mode Address mechanism, described in Section 5.7.3.1, controls the access.
- If EA0=1, bits 4:63 of the effective address are used as the real address for the access.

MSR_HV=0

- If VPM0=0, the Offset Real Mode Address mechanism, described in Section 5.7.3.2, controls the access.
- If VPM0=1, the Virtual Real Mode Addressing mechanism, described in Section 5.7.3.4, controls the access.

### 5.7.3.1 Hypervisor Offset Real Mode Address

If MSR_HV = 1 and EA0 = 0, the access is controlled by the contents of the Hypervisor Real Mode Offset Register, as follows.

**Hypervisor Real Mode Offset Register (HRMOR)**

Bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the HRMOR, and the 60-bit result is used as the real address for the access. The supported offset values are all values of the form \(i \times 2^r\), where \(0 \leq i < 2^j\), and \(j\) and \(r\) are implementation-dependent values having the properties that \(12 \leq r \leq 26\) (i.e., the minimum offset granularity is 4 KB and the maximum offset granularity is 64 MB) and \(j+r = m\), where the real address size supported by the implementation is \(m\) bits.

---

#### Programming Note

\(\text{EA}_{4:63}\) should equal \(60\times 0\). If this condition is satisfied, ORing the effective address with the offset produces a result that is equivalent to adding the effective address and the offset.

If \(m<60\), \(\text{EA}_{4:63-m}\) and \(\text{HRMOR}_{4:63-m}\) must be zeros.

---

### 5.7.3.2 Offset Real Mode Address

If VPM0=0 and MSR_HV=0, the access is controlled by the contents of the Real Mode Limit Selector and Real Mode Offset Register, as specified below, and the set of storage locations accessible by code is referred to as the Real Mode Area (RMA).

**Real Mode Limit Selector (RMLS)**

If bits 4:63 of the effective address for the access are greater than or equal to the value (limit) represented by the contents of the LPCR\(_{RMLS}\), the access causes a storage exception (see Section 5.7.9.3). In this comparison, if \(m<60\), bits 4:63-m of the effective address may be ignored (i.e., treated as if they were zeros), where the real address size supported by the implementation is \(m\) bits. The supported limit values are of the form \(2^j\), where \(12 \leq j \leq 60\). Subject to the preceding sentence, the number and values of the limits supported are implementation-dependent.

**Real Mode Offset Register (RMOR)**

If the access is permitted by the LPCR\(_{RMLS}\), bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the RMOR, and the low-order \(m\) bits of the 60-bit result are used as the real address for the access. The supported offset values are all values of the form \(i \times 2^s\), where \(0 \leq i < 2^k\), and \(k\) and \(s\) are implementation-dependent values having the properties that \(2^s\) is the minimum limit value supported by the implementation (i.e., the minimum value representable by the contents of the LPCR\(_{RMLS}\)) and \(k+s = m\).

---

#### Programming Note

The offset specified by the RMOR should be a non-zero multiple of the limit specified by the RMLS. If these registers are set thus, ORing the effective address with the offset produces a result that is equivalent to adding the effective address and the offset. (The offset must not be zero, because real page 0 contains the fixed interrupt vectors and real pages 1 and 2 may be used for implementation-specific purposes; see Section 5.7.4, "Address Ranges Having Defined Uses" on page 895.)
5.7.3.3 Storage Control Attributes for Accesses in Real and Hypervisor Real Addressing Modes

Storage accesses in hypervisor real addressing mode are performed as though all of storage had the following storage control attributes, except as modified by the Hypervisor Real Mode Storage Control facility (see Section 5.7.3.3.1). (The storage control attributes are defined in Book II.)

- not Write Through Required
- not Caching Inhibited, for instruction fetches
- not Caching Inhibited, for data accesses except those caused by the Load/Store Caching Inhibited instructions; Caching Inhibited, for data accesses caused by the Load/Store Caching Inhibited instructions
- Memory Coherence Required, for data accesses
- Guarded
- not SAO

Storage accesses in real addressing mode are performed as though all of storage had the following storage control attributes. (Such accesses use the Offset Real Mode Address mechanism.)

- not Write Through Required
- not Caching Inhibited
- Memory Coherence Required, for data accesses
- not Guarded
- not SAO

Additionally, storage accesses in real or hypervisor real addressing modes are performed as though all storage was not No-execute.

Programming Note

Because storage accesses in real addressing mode and hypervisor real addressing mode do not use the SLB or the Page Table, accesses in these modes bypass all checking and recording of information contained therein (e.g., storage protection checks that use information contained therein are not performed, and reference and change information is not recorded).

5.7.3.3.1 Hypervisor Real Mode Storage Control

The Hypervisor Real Mode Storage Control facility provides a means of specifying portions of real storage that are treated as non-Guarded in hypervisor real addressing mode. For the first technique, the facility provides for the specification, at coarse granularity, of the boundary between non-Guarded and Guarded real storage. Any storage location below the specified boundary is treated as non-Guarded in hypervisor real addressing mode, and any storage location at or above the boundary is treated as Guarded in hypervisor real addressing mode. For the second technique, the facility divides real storage into history blocks, in implementation-specific sizes. The history for instruction fetches is tracked separately from that for data accesses. If there is no instruction fetch history for a block and it is the target of an instruction fetch, the access is performed as though the block is Guarded, but the block is treated as non-Guarded for subsequent instruction fetches on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using a Load/Store Caching Inhibited instruction, the access is performed as though the block is Guarded, and the block is treated as Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using any other Load or Store instruction, the access is performed as though the block is Guarded, but the block is treated as non-Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain.

The storage location specified by a Load/Store Caching Inhibited instruction must not be in storage that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded. If the second technique is used, the storage location specified by any other Load or Store instruction must not be in storage that is specified by the Hypervisor Real Mode Storage Control facility to be treated as Guarded. (For the second technique, "specified by the Hypervisor Real Mode Storage Control facility" means "specified in a history block"). For the second technique, the history can be erased using an slbia instruction; see See Section 5.9.3.1.
The facility does not apply to implicit accesses to the Page Table performed during address translation or in recording reference and change information. These accesses are performed as described in Section 5.7.3.5.

The second caution is to avoid storage paradoxes that result from a caching-inhibited access to a location that is held in a cache. The nature of this caution and its solution are described in Section 5.8.2.2, “Altering the Storage Control Bits”. The minimum granularity for concern is the history block, but may be larger, depending on extant translations to the storage in question. Since the consistency of instruction storage is managed by software and hypervisor real mode instruction fetches are always not Caching Inhibited, instruction fetches are also irrelevant to this caution.

The preceding capability can be used to improve the performance of hypervisor software that runs in hypervisor real addressing mode, by causing accesses to instructions and data that occupy well-behaved storage to be treated as non-Guarded.

5.7.3.4 Virtual Real Mode Addressing Mechanism

If VPM0=1, MSR\textsubscript{e}=0, and MSR\textsubscript{DR}=0 or MSR\textsubscript{IR}=0 as appropriate for the type of access, the access is said to be made in virtual real addressing mode and is controlled by the mechanism specified below. The set of storage locations accessible by code referred to as the Virtualized Real Mode Area (VRMA).

In virtual real addressing mode, address translation, storage protection, and reference and change recording are handled as follows.

- Address translation and storage protection are handled as if address translation were enabled, except that translation of effective addresses to virtual addresses use the SLBE values in Figure 18 instead of the entry in the SLB corresponding to the ESID. In this translation, bits 0:23 of the effective address are ignored (i.e. treated as if they were 0s), bits 24:63-m may be ignored if m < 40, and the Virtual Page Class Key Protection mechanism does not apply.

The Virtual Page Class Key Protection mechanism does not apply because the authority mask that an OS has set for application programs executing with address translation enabled may not be the same as the authority mask required by the OS when address translation is disabled, such as when first entering an interrupt handler.

Reference and change recording are handled as if address translation were enabled.

Figure 18. SLBE for VRMA
5.7.3.5 Storage Control Attributes for Implicit Storage Accesses

Implicit accesses to the Page Table during address translation and in recording reference and change information are performed as though the storage occupied by the Page Table had the following storage control attributes.

- not Write Through Required
- not Caching Inhibited
- Memory Coherence Required
- not Guarded
- not SAO

The definition of “performed” given in Book II applies also to these implicit accesses; accesses for performing address translation are considered to be loads in this respect, and accesses for recording reference and change information are considered to be stores. These implicit accesses are ordered by the \textit{ptesync} instruction as described in Section 5.9.2.

5.7.4 Address Ranges Having Defined Uses

The address ranges described below have uses that are defined by the architecture.

- Fixed interrupt vectors
  
  Except for the first 256 bytes, which are reserved for software use, the real page beginning at real address 0x0000_0000_0000_0000 is either used for interrupt vectors or reserved for future interrupt vectors.

- Implementation-specific use
  
  The two contiguous real pages beginning at real address 0x0000_0000_0000_1000 are reserved for implementation-specific purposes.

- Offset Real Mode interrupt vectors
  
  The real pages beginning at the real address specified by the HRMOR and RMOR are used similarly to the page for the fixed interrupt vectors.

- Relocated interrupt vectors
  
  Depending on the values of MSR\textsubscript{IR DR} and LPCR\textsubscript{AIL} and on whether the specific interrupt will cause MSR\textsubscript{HV} to change, either the virtual page containing the byte addressed by effective address 0x0000_0000_0001_8000 or the virtual page containing the byte addressed by effective address 0xc000_0000_0000_4000 may be used similarly to the page for the fixed interrupt vectors. (See Section 2.2.)

- Page Table
  
  A contiguous sequence of real pages beginning at the real address specified by SDR1 contains the Page Table.

5.7.5 Address Translation Overview

The effective address (EA) is the address generated by the hardware for an instruction fetch or for a data access. If address translation is enabled, this address is passed to the Address Translation mechanism, which attempts to convert the address to a real address which is then used to access storage.

The first step in address translation is to convert the effective address to a virtual address (VA), as described in Section 5.7.6. The second step, conversion of the virtual address to a real address (RA), is described in Section 5.7.7.

If the effective address cannot be translated, a storage exception (see Section 5.2) occurs.

Figure 19 gives an overview of the address translation process.
5.7.6 Virtual Address Generation

Conversion of a 64-bit effective address to a virtual address is done by searching the Segment Lookaside Buffer (SLB) as shown in Figure 20.

5.7.6.1 Segment Lookaside Buffer (SLB)

The Segment Lookaside Buffer (SLB) specifies the mapping between Effective Segment IDs (ESIDs) and Virtual Segment IDs (VSIDs). The number of SLB entries is implementation-dependent, except that all implementations provide at least 32 entries.

The contents of the SLB are managed by software, using the instructions described in Section 5.9.3.1. See Chapter 12. “Synchronization Requirements for Context Alterations” on page 1009 for the rules that software must follow when updating the SLB.

SLB Entry

Each SLB entry (SLBE, sometimes referred to as a “segment descriptor”) maps one ESID to one VSID. Figure 21 shows the layout of an SLB entry.
All other fields are reserved. B₀ (SLBE₃₇) is treated as a reserved field.

Figure 21. SLB Entry

Instructions cannot be executed from a No-execute (N=1) segment.

Segments may contain a mixture of page sizes. The L and LP bits specify the base virtual page size that the segment may contain. The SLBL||LP encodings are those shown in Figure 22. The base virtual page size (also referred to as the “base page size”) is the smallest virtual page size for the segment. The base virtual page size is 2ᵇ bytes. The actual virtual page size (also referred to as the “actual page size” or “virtual page size”) is specified by PTEL LP.

All other fields are reserved. B₀ (SLBE₃₇) is treated as a reserved field.

Figure 22. Page Size Encodings

<table>
<thead>
<tr>

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:35</td>
<td>ESID</td>
<td>Effective Segment ID</td>
</tr>
<tr>
<td>36</td>
<td>V</td>
<td>Entry valid (V=1) or invalid (V=0)</td>
</tr>
<tr>
<td>37:38</td>
<td>B</td>
<td>Segment Size Selector</td>
</tr>
</tbody>
</table>
| 0b00 - 256 MB (s=28)  
0b01 - 1 TB (s=40)  
0b10 - reserved  
0b11 - reserved |
| 39:88 | VSID | Virtual Segment ID |
| 89    | Kₛ | Supervisor (privileged) state storage key (see Section 5.7.9.2) |
| 90    | Kₚ | Problem state storage key (See Section 5.7.9.2) |
| 91    | N  | No-execute segment if N=1 |
| 92    | L  | Virtual page size selector bit 0 |
| 93    | C  | Class |
| 95:96 | LP | Virtual page size selector bits 1:2 |

For each SLB entry, software must ensure the following requirements are satisfied.

- L||LP contains a value supported by the implementation.
- The base virtual page size selected by the L and LP fields does not exceed the segment size selected by the B field.
- If s=40, the following bits of the SLB entry contain 0s.
  - ESID₂₄:₃₅
  - VSID₈:₉₉

The bits in the above two items are ignored by the hardware.

The Class field of the SLBE is used in conjunction with the slbie and slbia instructions (see Section 5.9.3.1). “Class” refers to a grouping of SLB entries and implementation-specific lookaside information so that only entries in a certain group need be invalidated and others might be preserved. The Class value assigned to an implementation-specific lookaside entry derived from an SLB entry must match the Class value of that SLB entry. The Class value assigned to an implementation-specific lookaside entry that is not derived from an SLB entry (such as real mode address “translations”) is 0.

Software must ensure that the SLB contains at most one entry that translates a given effective address, and that if the SLB contains an entry that translates a given effective address, then any previously existing translation of that effective address has been invalidated. An attempt to create an SLB entry that violates this requirement may cause a Machine Check.

5.7.6.2 SLB Search

When the hardware searches the SLB, all entries are tested for a match with the EA. For a match to exist, the following conditions must be satisfied for indicated fields in the SLBE.

- V=1
- ESID₀:₆₃=EA₀:₆₃, where the value of s is specified by the B field in the SLBE being tested

If no match is found, the search fails. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the SLB search succeeds, the virtual address (VA) is formed from the EA and the matching SLB entry fields as follows.

For each SLB entry, software must ensure the following requirements are satisfied.

- L||LP contains a value supported by the implementation.
- The base virtual page size selected by the L and LP fields does not exceed the segment size selected by the B field.
- If s=40, the following bits of the SLB entry contain 0s.
  - ESID₂₄:₃₅
  - VSID₈:₉₉

The bits in the above two items are ignored by the hardware.

The Class field of the SLBE is used in conjunction with the slbie and slbia instructions (see Section 5.9.3.1). “Class” refers to a grouping of SLB entries and implementation-specific lookaside information so that only entries in a certain group need be invalidated and others might be preserved. The Class value assigned to an implementation-specific lookaside entry derived from an SLB entry must match the Class value of that SLB entry. The Class value assigned to an implementation-specific lookaside entry that is not derived from an SLB entry (such as real mode address “translations”) is 0.

Software must ensure that the SLB contains at most one entry that translates a given effective address, and that if the SLB contains an entry that translates a given effective address, then any previously existing translation of that effective address has been invalidated. An attempt to create an SLB entry that violates this requirement may cause a Machine Check.

5.7.6.2 SLB Search

When the hardware searches the SLB, all entries are tested for a match with the EA. For a match to exist, the following conditions must be satisfied for indicated fields in the SLBE.

- V=1
- ESID₀:₆₃=EA₀:₆₃, where the value of s is specified by the B field in the SLBE being tested

If no match is found, the search fails. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the SLB search succeeds, the virtual address (VA) is formed from the EA and the matching SLB entry fields as follows.
VA=VSID_{0:77} \parallel EA_{64:63}

The Virtual Page Number (VPN) is bits 0:77-p of the virtual address. The value of p is the actual virtual page size specified by the PTE used to translate the virtual address (see Section 5.7.7.1). If SLBEN = 1, the N (No-execute) value used for the storage access is 1.

If the SLB search fails, a segment fault occurs. This is an Instruction Segment exception or a Data Segment exception, depending on whether the effective address is for an instruction fetch or for a data access.

5.7.7 Virtual to Real Translation

Conversion of a 78-bit virtual address to a real address is done by searching the Page Table as shown in Figure 23.
Figure 23. Translation of 78-bit virtual address to 60-bit real address
5.7.7.1 Page Table

The Hashed Page Table (HTAB) is a variable-sized data structure that specifies the mapping between virtual page numbers and real page numbers, where the real page number of a real page is bits 0:47 of the address of the first byte in the real page. The HTAB's size can be any size $2^n$ bytes where $18 \leq n \leq 46$. The HTAB must be located in storage having the storage control attributes that are used for implicit accesses to it (see Section 5.7.3.5). The starting address must be a multiple of its size unless the implementation supports the Server.Relaxed Page Table Alignment category, in which case its starting address is a multiple of $2^{18}$ bytes (see Section 5.7.7.4).

The HTAB contains Page Table Entry Groups (PTEGs). A PTEG contains 8 Page Table Entries (PTEs) of 16 bytes each; each PTEG is thus 128 bytes long. PTEGs are entry points for searches of the Page Table.

See Section 5.10 for the rules that software must follow when updating the Page Table.

**Programming Note**

The Page Table must be treated as a hypervisor resource (see Chapter 2), and therefore must be placed in real storage to which only the hypervisor has write access. Moreover, the contents of the Page Table must be such that non-hypervisor software cannot modify storage that contains hypervisor programs or data.

### Page Table Entry

Each Page Table Entry (PTE) maps one VPN to one RPN. Figure 24 shows the layout of a PTE. This layout is independent of the Endian mode of the thread.

</tr>
</tbody>
</table>

**Programming Note**

The H bit in the Page Table entry should not be set to one unless the secondary Page Table search has been enabled.

If $b<23$, the Abbreviated Virtual Address (AVA) field contains bits 0:54 of the VA. Otherwise bits 0:77-b of the AVA field contain bits 0:77-b of the VA, and bits 78-b:54 of the AVA field must be zero.

**Programming Note**

The AVA field omits the low-order 23 bits of the VA. These bits are not needed in the PTE, because the low-order $b$ of these bits are part of the byte offset into the virtual page and, if $b<23$, the high-order 23-b of these bits are always used in selecting the PTEGs to be searched (see Section 5.7.7.3).

On implementations that support a virtual address size of only $n$ bits, $n<78$, bits 0:77-$n$ of the AVA field must be zeros.

A virtual page is mapped to a sequence of $2^{p-12}$ contiguous real pages such that the low-order $p$-12 bits of the real page number of the first real page in the sequence are 0s.

PTEL LP specify both a base virtual page size (henceforth referred to as the "base page size") and an actual virtual page size (henceforth referred to as the "actual page size" or "virtual page size"). The actual page size is the size of the virtual page mapped by the PTE. The base page size is the smallest actual page size that a segment can contain. See Section 5.7.6.

If PTEL=0, the base virtual page size and actual virtual page size are 4KB, and ARPN concatenated with LP (ARPNNILP) contains the page number of the real page that maps the virtual page described by the entry.

If PTEL=1, the base page size and actual page size are specified by PTELP. In this case, the contents of PTELP have the format shown in Figure 25. Bits labelled "r" are...
bits of the real page number. Bits labelled “z” specify the base page size and actual page size. The values of the “z” bits used to specify each size are implementation-dependent. The values of the “z” bits used to specify each size, along with all possible values of “r” bits in the LP field, must result in LP values distinct from other LP values for other sizes. Actual page sizes 4KB and 64KB are always supported; other actual page sizes are implementation-dependent. If PTEI=1, the actual page size must be greater than 4 KB. Which combinations of different base page size and actual page size are supported is implementation-dependent, except that the combination of a base page size of 4 KB with an actual page size of 64 KB is always supported.

\[
\text{PTE}_{LP} \quad \text{actual page size}
\]

- \(rrrr\_rrrz\) \(\geq 8\) KB
- \(rrrr\_rrzz\) \(\geq 16\) KB
- \(rrrr\_rrzz\) \(\geq 32\) KB
- \(rrrr\_zzzz\) \(\geq 64\) KB
- \(rrrz\_zzzz\) \(\geq 128\) KB
- \(rrzz\_zzzz\) \(\geq 256\) KB
- \(rzzz\_zzzz\) \(\geq 512\) KB
- \(zzzz\_zzzz\) \(\geq 1\) MB

\[
\text{Programming Note}
\]

Instructions cannot be executed from a No-execute (N=1) page.

**Page Table Size**

The number of entries in the Page Table directly affects performance because it influences the hit ratio in the Page Table and thus the rate of page faults. If the table is too small, it is possible that not all the virtual pages that actually have real pages assigned can be mapped via the Page Table. This can happen if too many hash collisions occur and there are more than 16 entries for the same primary/secondary pair of PTEGs (when the secondary Page Table search is enabled) or more than 8 entries for the same primary PTEG (when the secondary Page Table search is disabled).

While this situation cannot be guaranteed not to occur for any size Page Table, making the Page Table larger than the minimum size (see Section 5.7.7.2) will reduce the frequency of occurrence of such collisions.

**5.7.7.2 Storage Description**

**Register 1**

The Storage Description Register 1 (SDR1) register is shown in Figure 26.

<table>

**Figure 26. SDR1**

SDR1 is a hypervisor resource; see Chapter 2.

The HTABORG field in SDR1 contains the high-order 42 bits of the 60-bit real address of the Page Table. The Page Table is thus constrained to lie on a \(2^{18}\) byte (256 KB) boundary at a minimum. At least 11 bits from the hash function (see Figure 23) are used to index into the Page Table. The minimum size Page Table is 256 KB (\(2^{18}\) PTEGs of 128 bytes each).

**Programming Note**

Implementations often have implementation-dependent lookaside buffers (e.g. TLBs and ERATs) used to cache translations of recently used storage addresses. Mapping virtual storage to large pages may increase the effectiveness of such lookaside buffers, improving performance, because it is possible for such buffers to translate a larger range of addresses, reducing the frequency that the Page Table must be searched to translate an address.

**Programming Note**

If large pages are not used, it is recommended that the number of PTEGs in the Page Table be at least half the number of real pages to be accessed. For example, if the amount of real storage to be accessed is \(2^{31}\) bytes (2 GB), then we have \(2^{31-12}=2^{19}\) real pages. The minimum recommended Page Table size would be \(2^{18}\) PTEGs, or \(2^{25}\) bytes (32 MB).

The actual page size specified by a given PTE\(_{LP}\) format is at least \(2^{12}\times(8-c)\), where \(c\) is the number of \(r\) bits in the format.
The Page Table can be any size $2^n$ bytes where $18 \leq n \leq 46$. As the table size is increased, more bits are used from the hash to index into the table and the value in HTABORG must have more of its low-order bits equal to 0 unless the implementation supports the Server.Relaxed Page Table Alignment category; see Section 5.7.7.4.

The HTABSIZE field in SDR1 contains an integer giving the number of bits (in addition to the minimum of 11 bits) from the hash that are used in the Page Table index. This number must not exceed 28. HTABSIZE is used to generate a mask of the form $0b00...011...1$, which is a string of $28 - \text{HTABSIZE}$ 0-bits followed by a string of HTABSIZE 1-bits. The 1-bits determine which additional bits (beyond the minimum of 11) from the hash are used in the index (see Figure 23). The number of low-order 0 bits in HTABORG must be greater than or equal to the value in HTABSIZE.

On implementations that support a real address size of only m bits, $m < 60$, bits $0:59-m$ of the HTABORG field are treated as reserved bits, and software must set them to zeros.

### Programming Note

Let $n$ equal the virtual address size (in bits) supported by the implementation. If $n < 67$, software should set the HTABSIZE field to a value that does not exceed $n - 39$. Because the high-order 78-n bits of the VSID are assumed to be zeros, the hash value used in the Page Table search will have the high-order 67-n bits either all 0s (primary hash; see Section 5.7.7.3) or all 1s (secondary hash). If HTABSIZE > $n-39$, some of these hash value bits will be used to index into the Page Table, with the result that certain PTEGs will not be searched.

### Example:

Suppose that the Page Table is 16,384 ($2^{14}$) 128-byte PTEGs, for a total size of $2^{21}$ bytes (2 MB). A 14-bit index is required. Eleven bits are provided from the hash to start with, so 3 additional bits from the hash must be selected. Thus the value in HTABSIZE must be 3 and the value in HTABORG must have its low-order 3 bits (bits 43:45 of SDR1) equal to 0. This means that the Page Table must begin on a $2^{3+11+7} = 2^{21} = 2$ MB boundary.

### 5.7.7.3 Page Table Search

When the hardware searches the Page Table, the accesses are performed as described in Section 5.7.3.5.

An outline of the HTAB search process is shown in Figure 23. If the implementation supports the Server.Relaxed Page Table Alignment category see Section 5.7.7.4. Up to two hash functions are used to locate a PTE that may translate the given virtual address.

1. A 39-bit hash value is computed from the VA. The value of $s$ is the value specified in the SLBE that was used to generate the virtual address; the value of $b$ is equal to $\log_2$(base page size specified in the SLBE that was used to translate the address). **Primary Hash:**

   If $s=28$, the hash value is computed by Exclusive ORing $VA_{11:49}$ with $(11+b0||VA_{50:77-b})$

   If $s=40$, the hash value is computed by Exclusive ORing the following three quantities: $(VA_{24:37}||VA_{38:77-b}), (0||VA_{0:37})$, and $(b-10||VA_{38:77-b})$

   The 60-bit real address of a PTEG is formed by concatenating the following values:
   - Bits 4:17 of SDR1 (the high-order 14 bits of HTABORG).
   - Bits 0:27 of the 39-bit hash value ANDed with the mask generated from bits 59:63 of SDR1 (HTABSIZE) and then ORed with bits 18:45 of SDR1 (the low-order 28 bits of HTABORG).
   - Bits 28:38 of the 39-bit hash value.
   - Seven 0-bits.

   This operation identifies a particular PTEG, called the “primary PTEG”, whose eight PTEs will be tested.

2. **Secondary Hash:**

   If the secondary Page Table search is enabled (LPCRTE=0), perform the secondary hash function as follows; otherwise do not perform step 2 and proceed to step 3 below.

   If $s=28$, the hash value is computed by taking the ones complement of the Exclusive OR of $VA_{11:49}$ with $(11+b0||VA_{50:77-b})$

   If $s=40$, the hash value is computed by taking the ones complement of the Exclusive OR of the following three quantities: $(VA_{24:37}||VA_{38:77-b}), (0||VA_{0:37})$, and $(b-10||VA_{38:77-b})$

   The 60-bit real address of a PTEG is formed by concatenating the following values:
   - Bits 4:17 of SDR1 (the high-order 14 bits of HTABORG).
   - Bits 0:27 of the 39-bit hash value ANDed with the mask generated from bits 59:63 of SDR1 (HTABSIZE) and then ORed with bits 18:45 of SDR1 (the low-order 28 bits of HTABORG).
   - Bits 28:38 of the 39-bit hash value.
   - Seven 0-bits.

   This operation identifies the “secondary PTEG”.

3. As many as 8 PTEs in the primary PTEG and, if the secondary Page Table search is enabled, 8 PTEs in the secondary PTEG are tested to determine if any translate the given virtual address. Let $q = \text{minimum}(54, 77-b)$. For a match to exist, the
following conditions must be satisfied, where SLBE is the SLBE used to form the virtual address.

- \( PTE_H = 0 \) for the primary PTEG, \( PTE_H = 1 \) for the secondary PTEG
- \( PTE_V = 1 \)
- \( PTE_B = SLBE_B \)
- \( PTE_AVA[0:q] = VA_0:q \)
- if \( b = 12 \) then
  \( (PTE_L = 0) \land (PTE_LP \text{ specifies the 4KB base page size}) \)
else
  \( (PTE_L = 1) \land (PTE_LP \text{ specifies the base page size specified by } SLBE || LP) \)

If no match is found, the search fails. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the Page Table search succeeds, the real address (\( RA \)) is formed by concatenating bits 0:59-p of ARPN||LP from the matching PTE with bits 64-p:63 of the effective address (the byte offset), where the p value is the \( \log_2 \) (actual page size specified by \( PTE_L || LP \)).

\[
RA = (ARPN \ || \ LP)[0:59-p] \ || \ EA[64-p:63]
\]

### Programming Note

If \( PTE_L = 0 \), the actual page size (and base page size) are 4 KB. Otherwise the actual page size and base page size are specified by \( PTE_LP \).

Since hardware searches the Page Table using a value of \( b \) equal to \( \log_2 \) (base page size specified in the SLBE that was used to translate the address) regardless of the actual page size, the hardware page table search will identify different PTEs for VAs in different \( 2^b \)-byte blocks of the virtual page if the actual page size is larger than the base page size. Therefore, there may need to be a valid PTE corresponding to each \( 2^b \)-byte block of the virtual page that is referenced. For an actual page size that is larger than \( 2^{23} \) (8 MB), the \( PTE_AVA \) will differ among some or all of these PTEs. Depending on the Page Table size, some or all of these PTEs may be in the same PTEG. Any such PTEs that are in the same PTEG will differ in the value of \( PTE_H \) or \( PTE_AVA \) or both.

All PTEs for the same virtual page should have the same values in the Page Protection, KEY, ARPN, WIMG, and N fields. A set of values from any one of the PTEs that maps the virtual page may be used for an access in the virtual page since lookahead buffer information may be used to translate the virtual address.

To avoid creating multiple matching PTEs, software should not create PTEs for each of two different virtual pages that overlap in the virtual address space. If the virtual page sizes differ, two virtual pages overlap if the values of virtual address bits 0:77-p for both virtual pages are the same, where \( 2^p \) is the actual virtual page size of the larger page.

The \( N \) (No-execute) value used for the storage access is the result of ORing the \( N \) bit from the matching PTE with the \( N \) bit from the SLB entry that was used to translate the effective address.

### Programming Note

The value of \( b \) used when searching the Page Table to identify the PTEGs is \( \log_2 \) (base page size). Since a segment may contain pages of different sizes, the hardware searches for PTEs specifying pages of any supported size greater than or equal to the base page size, and the real address is formed using the value of \( p \) specified by the matching PTE.

A virtual page of \( 2^p \) bytes in a segment with a base page size of \( 2^b \) bytes may be mapped by as many as \( 2^{(p-b)} \) PTEs.

If the Page Table search fails, a page fault occurs. This is a Hypervisor Instruction Storage exception or a Hypervisor Data Storage exception, depending on
whether the effective address is for an instruction fetch or for a data access. The N value used for the storage access is the N bit from the SLB entry that was used to translate the effective address.

Translation Lookaside Buffer

Conceptually, the Page Table is searched by the address relocation hardware to translate every reference. For performance reasons, the hardware usually keeps a Translation Lookaside Buffer (TLB) that holds PTEs that have recently been used. Even though multiple PTEs may be needed for a virtual page whose size is larger than the base page size, one TLB entry derived from a single PTE may be used to translate all of the virtual addresses in the entire virtual page. The TLB is searched prior to searching the Page Table. As a consequence, when software makes changes to the Page Table it must perform the appropriate TLB invalidate operations to maintain the consistency of the TLB with the Page Table (see Section 5.10).

In the TLB search, the match criteria include virtual address bits 0:(77-q) where q is an implementation-dependent integer such that \( b \leq q \leq p \). As a result of a Page Table search, multiple matching TLB entries are not created for the same virtual page, except that multiple matching TLB entries may be created if the Page Table contains PTEs that map different-sized virtual pages that overlap in the virtual address space. (If the virtual page sizes differ, two virtual pages overlap if the values of virtual address bits 0:77-p for both virtual pages are the same, where \( 2^p \) is the actual virtual page size of the larger page.) If a TLB search finds multiple matching TLB entries created from such PTEs, one of the matching TLB entries is used as if it were the only matching entry, or a Machine Check occurs.

As a result of a Page Table search in a Page Table that does not contain different-sized virtual pages that overlap, it is implementation-dependent whether multiple non-matching TLB entries are created for the same virtual page. However, in this case if multiple TLB entries are created for a given virtual page, at most one matching TLB entry is created for any given virtual address in that virtual page, and q for that TLB entry is less than p.

An implementation may associate each of its TLB entries with the partition for which the TLB entry was created, so that the entries can be retained while other partitions are executing. In this case, when a valid TLB entry is created, the LPID value from LPIDR is written into the TLB entry.

Programming Notes

1. Page Table Entries may or may not be cached in a TLB.
2. It is possible that the hardware implements more than one TLB, such as one for data and one for instructions. In this case the size and shape of the TLBs may differ, as may the values contained therein.
3. Use the `tlbie` or `tlbia` instruction to ensure that the TLB no longer contains a mapping for a particular virtual page.

5.7.4 Relaxed Page Table Alignment [Category: Server.Relaxed Page Table Alignment]

The Page Table can be aligned on any \( 2^{18} \) byte (256 KB) boundary regardless of the HTAB size.

Section 5.7.7.2 describes the Storage Description Register, which includes the HTABORG field. That description generally applies except for the following difference. As the Page Table size is increased beyond 256 KB, the value in HTABORG need not have more of its low-order bits equal to 0. Instead, \( (\text{HTABORG} \parallel 180) \) is the real address of the start of the Page Table regardless of the Page Table size.

A Page Table search is performed as described in Section 5.7.7.3 except the 60-bit real address of a PTEG for both the primary and, if the secondary Page Table search is enabled, the secondary hash is formed by concatenating the following values:

- Bits 0:27 of the 39-bit appropriate primary or secondary hash value ANDed with the mask generated from bits 59:63 of SDR1 (HTAB-SIZE) and then added to the value of bits 4:45 of SDR1 (HTABORG). This part of the real address differs from Section 5.7.7.2.
- Bits 28:38 of the 39-bit hash value.
- Seven 0-bits.

An outline of the PTEG real address computation is shown in Figure 23.

5.7.8 Reference and Change Recording

If address translation is enabled, Reference (R) and Change (C) bits are updated in any one of what could be multiple Page Table Entries that map the virtual page that is being accessed. If the storage operand of a `Load` or `Store` instruction crosses a virtual page boundary, the accesses to the components of the operand in each page are treated as separate and independent.
accesses to each of the pages for the purpose of setting the Reference and Change bits.

Reference and Change bits are set by the hardware as described below. Setting the bits need not be atomic with respect to performing the access that caused the bits to be updated. An attempt to access storage may cause one or more of the bits to be set (as described below) even if the access is not performed. The bits are updated in the Page Table Entry if the new value would otherwise be different from the old value for the virtual page, as determined by examining either the Page Table Entry or any lookaside information for the virtual page (e.g., TLB) maintained by the hardware.

Reference Bit

The Reference bit is set to 1 if the corresponding access (load, store, or instruction fetch) is required by the sequential execution model and is performed. Otherwise the Reference bit may be set to 1 if the corresponding access is attempted, either in-order or out-of-order, even if the attempt causes an exception, except that the Reference bit is not set to 1 for the access caused by an indexed Move Assist instruction for which the XER specifies a length of zero.

Change Bit

The Change bit is set to 1 if a Store instruction is executed and the store is performed. Otherwise in general the Change bit may be set to 1 if a Store instruction is executed and the store is permitted by the storage protection mechanism and, if the Store instruction is executed out-of-order, the instruction would be required by the sequential execution model in the absence of the following kinds of interrupts:

- system-caused interrupts (see Section 6.4 on page 946)
- Floating-Point Enabled Exception type Program interrupts when the thread is in an Imprecise mode.

The only exception to the preceding statement is that the Change bit is not set to 1 if the instruction is a Store String Indexed instruction for which the XER specifies a length of zero.

Programming Note

A virtual page in a segment with a smaller base page size may be mapped by multiple PTEs. For each access of a virtual page, hardware may search the Page Table to update the R and C bits. If lookaside buffer information for the virtual page already indicates that all such bits to be set have already been set in a PTE that maps the virtual page, hardware need not make an update. Consider the following sequence of events:

1. A virtual page is mapped by 2 PTEs A and B and the R and C bits in both PTEs are 0.
2. A Load instruction accesses the virtual page and the R bit is updated in PTE A.
3. A Load instruction accesses the virtual page and the R bit is updated in PTE B.
4. A Store instruction accesses the virtual page and the C bit is updated in PTE B.
5. The virtual page is paged out. Software must examine both PTE A and B to get the state of the R and C bits for the virtual page.

Furthermore, if in event 2, PTE A was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur. Subsequently, if in event 3 or 4, PTE B was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur.
When the hardware updates the Reference and Change bits in the Page Table Entry, the accesses are performed as described in Section 5.7.3.5, “Storage Control Attributes for Implicit Storage Accesses” on page 895. The accesses may be performed using operations equivalent to a store to a byte, halfword, word, or doubleword, and are not necessarily performed as an atomic read/modify/write of the affected bytes.

These Reference and Change bit updates are not necessarily immediately visible to software. Executing a sync instruction ensures that all Reference and Change bit updates associated with address translations that were performed, by the thread executing the sync instruction, before the sync instruction is executed will be performed with respect to that thread before the sync instruction’s memory barrier is created. There are additional requirements for synchronizing Reference and Change bit updates in multi-threaded systems; see Section 5.10, “Page Table Update Synchronization Requirements” on page 935.

When software refers to a Page Table Entry when MSRDR=1, the Reference and Change bits in the associated Page Table Entry are set as for ordinary loads and stores. See Section 5.10 for the rules software must follow when updating Reference and Change bits.

Figure 27 on page 907 summarizes the rules for setting the Reference and Change bits. The table applies to each atomic storage reference. It should be read from the top down; the first line matching a given situation applies. For example, if stwcx. fails due to both a storage protection violation and the lack of a reservation, the Change bit is not altered.

In the figure, the “Load-type” instructions are the Load instructions described in Books I, II, and III-S, eciwx, and the Cache Management instructions that are treated as Loads. The “Store-type” instructions are the Store instructions described in Books I, II, and III-S, ecowx, and the Cache Management instructions that are treated as Stores. The “ordinary” Load and Store instructions are those described in Books I, II, and III-S. “set” means “set to 1”.

Even though the execution of a Store instruction causes the Change bit to be set to 1, the store might not be performed or might be only partially performed in cases such as the following.

- A Store Conditional instruction (stwcx. or stdcx.) is executed, but no store is performed.
- The Store instruction causes a Data Storage exception (for which setting the Change bit is not prohibited).
- The Store instruction causes an Alignment exception.
- The Page Table Entry that translates the virtual address of the storage operand is altered such that the new contents of the Page Table Entry preclude performing the store (e.g., the PTE is made invalid, or the PP bits are changed).

For example, when executing a Store instruction, the thread may search the Page Table for the purpose of setting the Change bit and then re-execute the instruction. When reexecuting the instruction, the thread may search the Page Table a second time. If the Page Table Entry has meanwhile been altered, by a program executing on another thread, the second search may obtain the new contents, which may preclude the store.

- A system-caused interrupt occurs before the store has been performed.

Because the sync instruction is execution synchronizing, the set of Reference and Change bit updates that are performed with respect to the thread executing the sync instruction before the memory barrier is created includes all Reference and Change bit updates associated with instructions preceding the sync instruction.

If a system-caused interrupt occurs before the store has been performed.

Programming Note

Because the sync instruction is execution synchronizing, the set of Reference and Change bit updates that are performed with respect to the thread executing the sync instruction before the memory barrier is created includes all Reference and Change bit updates associated with instructions preceding the sync instruction.

Even though the execution of a Store instruction causes the Change bit to be set to 1, the store might not be performed or might be only partially performed in cases such as the following.

- A Store Conditional instruction (stwcx. or stdcx.) is executed, but no store is performed.
- The Store instruction causes a Data Storage exception (for which setting the Change bit is not prohibited).
- The Store instruction causes an Alignment exception.
- The Page Table Entry that translates the virtual address of the storage operand is altered such that the new contents of the Page Table Entry preclude performing the store (e.g., the PTE is made invalid, or the PP bits are changed).

For example, when executing a Store instruction, the thread may search the Page Table for the purpose of setting the Change bit and then re-execute the instruction. When reexecuting the instruction, the thread may search the Page Table a second time. If the Page Table Entry has meanwhile been altered, by a program executing on another thread, the second search may obtain the new contents, which may preclude the store.

- A system-caused interrupt occurs before the store has been performed.
### Status of Access

</tbody>
</table>

^"Acc" means that it is acceptable to set the bit.

1 It is preferable not to set the bit.
2 If C is set, R is also set unless it is already set.
3 For Floating-Point Enabled Exception type Program interrupts, "imprecise" refers to the exception mode controlled by MSR^FEO FE1.
4 This case does not apply to the *Touch* instructions, because they do not cause a storage access.

---

Figure 27. Setting the Reference and Change bits
5.7.9 Storage Protection

The storage protection mechanism provides a means for selectively granting instruction fetch access, granting read access, granting write access, and prohibiting access to areas of storage based on a number of control criteria.

The operation of the storage protection mechanism depends on the contents of one or more of the following:

- MSR bits HV, IR, DR, PR
- the key bits in the associated SLB entry
- the page protection bits and key bits in the associated PTE
- the AMR, IAMR, AMOR, and UAMOR
- LPCR bit VPM0

The storage protection mechanism consists of the Virtual Page Class Key Protection mechanism, described in Section 5.7.9.1, and the Basic Storage Protection mechanism, described in Section 5.7.9.2 and Section 5.7.9.3.

When address translation is enabled for an access, the access is permitted if and only if the access is permitted by both the Virtual Page Class Key Protection mechanism and the Basic Storage Protection mechanism. When address translation is disabled for an access, the access is permitted if and only if the access is permitted by the Basic Storage Protection mechanism. If an instruction fetch is not permitted, an Instruction Storage exception or a Hypervisor Instruction Storage exception is generated. If a data access is not permitted, a Data Storage exception or a Hypervisor Data Storage exception is generated.

A protection domain is a maximal range of effective addresses for which variables related to storage protection can be independently specified (including by default, as in real and hypervisor real addressing modes), or a maximal range of addresses, effective or virtual, for which variables related to storage protection cannot be specified. Examples include: a segment, a virtual page (including for a virtualized Real Mode Area), the Real Mode Area (regardless of whether the RMA is virtualized), the effective address range 0:260-1 in hypervisor real addressing mode, and a maximal range of effective or virtual addresses that cannot be mapped to real addresses. A protection boundary is a boundary between protection domains.

5.7.9.1 Virtual Page Class Key Protection

The Virtual Page Class Key Protection mechanism provides the means to assign virtual pages to one of 32 classes, and to modify data access permissions for each class by modifying the Authority Mask Register (AMR), shown in Figure 28, and to modify instruction access permissions for each class by modifying the Instruction Authority Mask Register (IAMR) shown in Figure 29.

**Programming Note**

If address translation is disabled for a given access, the access is not affected by the Virtual Page Class Key Protection mechanism even if the access is made in virtual real addressing mode.

### Authority Mask Register

<table>

<td>Key31</td>
<td>Access mask for class number 31</td>
</tr>
</tbody>
</table>

**Figure 28. Authority Mask Register (AMR)**

The access mask for each class defines the access permissions that apply to loads and stores for which the virtual address is translated using a Page Table Entry that contains a KEY field value equal to the class number. The access permissions associated with each class are defined as follows, where AMR_{2n} and AMR_{2n+1} refer to the first and second bits of the access mask corresponding to class number n.

- A store is permitted if AMR_{2n}=0b0; otherwise the store is not permitted.
- A load is permitted if AMR_{2n+1}=0b0; otherwise the load is not permitted.

The AMR can be accessed using either SPR 13 or SPR 29. Access to the AMR using SPR 29 is privileged.

**Programming Note**

Because the AMR is part of the program context (if address translation is enabled), and because it is desirable for most application programmers not to have to understand the software synchronization requirements for context alterations (or the nuances of address translation and storage protection), operating systems should provide a system library program that application programs can use to modify the AMR.

Figure 29. Instruction Authority Mask Register (IAMR)

The access mask for each class defines the access permissions that apply to instruction fetches for which the virtual address is translated using a Page Table Entry that contains a KEY field value equal to the class number. The access permission associated with each class is defined as follows, where IAMR_{2n+1} refers to the bit of the access mask corresponding to class number $n$.

- An instruction fetch is permitted if IAMR_{2n+1} = 0b0; otherwise the instruction fetch is not permitted.

Access to the IAMR is privileged.

The Authority Mask Override Register (AMOR) and the User Authority Mask Override Register (UAMOR), shown in Figure 30 and Figure 31 respectively, can be used to restrict modifications (mtspr) of the AMR. Also, the AMOR can be used to restrict modifications of the UAMOR and IAMR. Access to both the AMOR and UAMOR is privileged. The AMOR is a hypervisor resource.

Figure 30. Authority Mask Override Register (AMOR)

Figure 31. User Authority Mask Override Register (UAMOR)

The bits of the AMOR and UAMOR are in 1-1 correspondence with the bits of the AMR (i.e., [U]AMOR$_i$ corresponds to AMR$_i$). The AMOR affects modifications of the AMR and UAMOR in privileged but non-hypervisor state; the UAMOR affects modifications of the AMR in problem state.

Similarly, the odd bits of the AMOR are in 1-1 correspondence with the odd bits of the IAMR (i.e., AMOR$_{2i+1}$ corresponds to IAMR$_{2i+1}$). The AMOR affects modifications of the IAMR in privileged but non-hypervisor state; the IAMR cannot be accessed in problem state.

- When mtspr specifying the AMR (using either SPR 13 or SPR 29) or the IAMR is executed in privileged but non-hypervisor state, the AMOR is used as a mask that controls which bits of the resulting AMR or IAMR contents come from register RS and which AMR or IAMR bits are not modified.
- Similarly, when mtspr specifying the AMR (using SPR 13) is executed in problem state, the UAMOR is used as a mask that controls which bits of the resulting AMR contents come from register RS and which AMR bits are not modified.

A complete description of these effects can be found in the description of the mtspr instruction on page 1053.

Software must ensure that both bits of each even/odd bit pair of the AMOR contain the same value. — i.e., the contents of register RS for mtspr specifying the AMOR must be such that (RS)$_{2n} = (RS)$_{2n+1}$ for every n in the range 0:31 — and likewise for the UAMOR. If this requirement is violated for the UAMOR the results of accessing the UAMOR (including implicitly by the hardware as described in the second item of the preceding list) are boundedly undefined; if the requirement is violated for the AMOR the results of accessing the AMOR (including implicitly by the hardware as described in the first and third items of the list) are undefined.

Version 2.07

Chapter 5. Storage Control 909
The preceding requirement permits designs to implement the AMOR and/or UAMOR as 32-bit registers — specifically, to implement only the even-numbered bits (or only the odd-numbered bits) of the register — in a manner such that the reduction, from the architecturally-required 64 bits to 32 bits, is not visible to (correct) software. This implementation technique saves space in the hardware. (A design that uses this technique does the appropriate “fan in/out” when the register is accessed, to provide the appearance, to (correct) software, of supporting all 64 bits of the register.)

Permitting designs to implement the [U]AMOR as 32-bit registers by virtue of the software requirement specified above, rather than by defining the [U]AMOR as 32-bit registers, permits the architecture to be extended in the future to support controlling modification of the “read access” AMR bits (the odd-numbered bits) independently from the “write access” AMR bits (the even-numbered bits), if that proves desirable. If this independent control does prove desirable, the only architecture change would be to eliminate the software requirement.

When modifying the AMOR and/or UAMOR, the hypervisor should ensure that the two registers are consistent with one another before giving control to a non-hypervisor program. In particular, the hypervisor should ensure that if AMOR$_i$=0 then UAMOR$_i$=0, for all $i$ in the range 0:63. (Having AMOR$_i$=0 and UAMOR$_i$=1 would permit problem state programs, but not the operating system, to modify AMR bit $i$.)
Programming Note

The Virtual Page Class Key Protection mechanism replaces the Data Address Compare mechanism that was defined in versions of the architecture that precede Version 2.04 (e.g., the two facilities use some of the same resources, as described below). However, the Virtual Page Class Key Protection mechanism can be used to emulate the Data Address Compare mechanism. Moreover, programs that use the Data Address Compare mechanism can be modified in a manner such that they will work correctly both on implementations that comply with versions of the architecture that precede Version 2.04 (and hence implement the Data Address Compare mechanism) and on implementations that comply with Version 2.04 of the architecture or with any subsequent version (and hence instead implement the Virtual Page Class Key Protection mechanism). The technique takes advantage of the facts that the SPR number for privileged access to the AMR (29) is the same as the SPR number for the Data Address Compare mechanism's ACCR (Address Compare Control Register), that KEY4 occupies the same bit in the PTE as the Data Address Compare mechanism's AC (Address Compare) bit, and that the definition of ACCR62:63 is very similar to the definition of each even-odd pair of AMR bits. The technique is as follows, where PTE1 refers to doubleword 1 of the PTE.

- Set bits 2:3 and 62:63 of SPR 29 (which is either the ACCR or the AMR) to x, where x is the desired 2-bit value for controlling Data Address Compare matches, and set bits 0:1 to 0s.
- Set PTE154 (which is either the AC bit or KEY4) to the same value that the AC bit would be set to, and set PTE12:3 (which are either RPN bits, that correspond to a real address size larger than the size supported by any implementation that supports the Data Address Compare mechanism, or KEY0:1) and PTE152:53 (which are either reserved bits or KEY2:3) to 0s.
- Use PTEKEY values 0 and 1 only for purposes of emulating the Data Address Compare mechanism, except that PTEKEY value 0 may also be used for any virtual pages for which it is desired that the Virtual Page Class Key Protection mechanism permit all accesses. Do not use PTEKEY =31.
- When a Hypervisor Data Storage interrupt occurs, if HDSISR42=1 then ignore the interrupt for Cache Management instructions other than dcbz. (These instructions can cause a virtual page class key protection violation but cannot cause a Data Address Compare match.) Otherwise forward the interrupt to the operating system, which will treat the interrupt as if a Data Address Compare match had occurred. (Note: Cases for which it is undefined whether a Data Address Compare match occurs do not necessarily cause a virtual page class key protection violation.)

(Because privileged software can access the AMR using either SPR 13 or SPR 29, it might seem that, when SPR 13 was added to the architecture (in Version 2.06), SPR 29 should have been removed. SPR 29 is retained for two reasons: first, to avoid requiring privileged software to change to use the newer SPR number; and second, to retain the ability to emulate the Data Address Compare mechanism as described above.)
An example of the use of the AMOR (and UAMOR) is to support lightweight partitions, here called "adjunct" partitions, that provide services (e.g., device drivers) to "client" partitions. The adjunct partition would be managed by the hypervisor. It would run in problem state with MSR$$_{HV}$$=0b11, thereby restricting the resources it can modify (MSR$$_{PR}$$=1) and causing its interrupts to go to the hypervisor (MSR$$_{HV}$$=1), and it would share a Page Table with the client partition it serves. Typically, each of the two partitions would have data storage that the other partition must not be able to access. The hypervisor can use the AMOR, UAMOR, AMR, and PTE KEY field to provide the required protection. (The adjunct partition's lightness of weight derives from not requiring an operating system, and especially from not requiring a full partition context switch (SLB flush, TLB flush, SDR1 change, etc.) when the client partition invokes the services of the adjunct partition.)

For example, suppose each of the two partitions must not be able to access any of the other partition's data storage. The hypervisor could use KEY value j for all data virtual pages that only the adjunct partition must be able to access. Before dispatching the client partition for the first time, the hypervisor would initialize the three registers as follows.

AMR: all 0s except bits 2j and 2j+1, which would contain 1s
UAMOR: all 0s
AMOR: all 1s except bits 2j and 2j+1, which would contain 0s

Before dispatching the adjunct partition, the hypervisor would set UAMOR to all 0s, and would set the AMR to all 1s except bits 2j and 2j+1, which would be set to 0s. (Because the adjunct partition would run in problem state, there is no need for the hypervisor to modify the AMOR, and the adjunct partition cannot modify the UAMOR.) In addition, the hypervisor would prevent the client partition from modifying or deleting PTEs that contain translations used by the adjunct partition.

(It may be desirable to avoid using KEY values 0, 1, and 31 for storage that only the adjunct partition can access, because these KEY values may be needed by the client partition to emulate the Data Address Compare mechanism, as described above. Also, old software, that was written for an implementation that complies with a version of the architecture that precedes Version 2.04 (the version in which virtual page class keys were added), effectively uses KEY 0 for all virtual pages.)

Initialization of the UAMOR to all 0s, by the hypervisor before dispatching a partition for the first time, as described in the preceding Programming Note, permits operating systems (in partitions that run in a compatibility mode corresponding to Version 2.06 of the architecture or a subsequent version) to migrate gradually to supporting problem state access to the AMR — specifically, to avoid having to be changed immediately to modify the UAMOR and to save the AMR contents when an interrupt occurs from problem state. Relatedly, having the UAMOR contain all 0s while an application program is running protects old application programs that are "AMR-unaware". In the absence of programming errors, such application programs would not attempt to read or modify the AMR. However, having the UAMOR contain all 0s protects such programs against modifying the AMR inadvertently.

Permitting an "AMR-unaware" application program to modify the AMR (inadvertently) is potentially harmful for the obvious reasons. (The program might set to 1 an AMR bit corresponding to accesses that are necessary in order for the program to work correctly.) Moreover, even for an operating system that includes support for problem state modification of the AMR, having the UAMOR contain all 0s allows the operating system to avoid saving and restoring the AMR for "AMR-unaware" application programs. Such an operating system would provide a system service program that allows an application program to declare itself to be "AMR-aware" — i.e., potentially to need to modify the AMR. When an application program invokes this service, the operating system would set the UAMOR to the non-zero value appropriate to the access authorities (load and/or store, for one or more key values) that the application program is allowed to modify, and thereafter would save and restore the AMR (and preserve the UAMOR) for this application program. (Having the UAMOR contain all 0s does not prevent an "AMR-unaware" program from reading the AMR, but inadvertently reading of the AMR is likely to be much less harmful than inadvertently modifying it.)

(For partitions that run in a compatibility mode corresponding to a version of the architecture that precedes Version 2.06, the PCR provides sufficient protection to application programs.)

### Programming Note

An example of the use of the AMOR (and UAMOR) is to support lightweight partitions, here called "adjunct" partitions, that provide services (e.g., device drivers) to "client" partitions. The adjunct partition would be managed by the hypervisor. It would run in problem state with MSR$$_{HV}$$=0b11, thereby restricting the resources it can modify (MSR$$_{PR}$$=1) and causing its interrupts to go to the hypervisor (MSR$$_{HV}$$=1), and it would share a Page Table with the client partition it serves. Typically, each of the two partitions would have data storage that the other partition must not be able to access. The hypervisor can use the AMOR, UAMOR, AMR, and PTE KEY field to provide the required protection. (The adjunct partition’s lightness of weight derives from not requiring an operating system, and especially from not requiring a full partition context switch (SLB flush, TLB flush, SDR1 change, etc.) when the client partition invokes the services of the adjunct partition.)

For example, suppose each of the two partitions must not be able to access any of the other partition's data storage. The hypervisor could use KEY value j for all data virtual pages that only the adjunct partition must be able to access. Before dispatching the client partition for the first time, the hypervisor would initialize the three registers as follows.

AMR: all 0s except bits 2j and 2j+1, which would contain 1s
UAMOR: all 0s
AMOR: all 1s except bits 2j and 2j+1, which would contain 0s

Before dispatching the adjunct partition, the hypervisor would set UAMOR to all 0s, and would set the AMR to all 1s except bits 2j and 2j+1, which would be set to 0s. (Because the adjunct partition would run in problem state, there is no need for the hypervisor to modify the AMOR, and the adjunct partition cannot modify the UAMOR.) In addition, the hypervisor would prevent the client partition from modifying or deleting PTEs that contain translations used by the adjunct partition.

(It may be desirable to avoid using KEY values 0, 1, and 31 for storage that only the adjunct partition can access, because these KEY values may be needed by the client partition to emulate the Data Address Compare mechanism, as described above. Also, old software, that was written for an implementation that complies with a version of the architecture that precedes Version 2.04 (the version in which virtual page class keys were added), effectively uses KEY 0 for all virtual pages.)

### Programming Note

Initialization of the UAMOR to all 0s, by the hypervisor before dispatching a partition for the first time, as described in the preceding Programming Note, permits operating systems (in partitions that run in a compatibility mode corresponding to Version 2.06 of the architecture or a subsequent version) to migrate gradually to supporting problem state access to the AMR — specifically, to avoid having to be changed immediately to modify the UAMOR and to save the AMR contents when an interrupt occurs from problem state. Relatedly, having the UAMOR contain all 0s while an application program is running protects old application programs that are "AMR-unaware". In the absence of programming errors, such application programs would not attempt to read or modify the AMR. However, having the UAMOR contain all 0s protects such programs against modifying the AMR inadvertently.

Permitting an "AMR-unaware" application program to modify the AMR (inadvertently) is potentially harmful for the obvious reasons. (The program might set to 1 an AMR bit corresponding to accesses that are necessary in order for the program to work correctly.) Moreover, even for an operating system that includes support for problem state modification of the AMR, having the UAMOR contain all 0s allows the operating system to avoid saving and restoring the AMR for "AMR-unaware" application programs. Such an operating system would provide a system service program that allows an application program to declare itself to be "AMR-aware" — i.e., potentially to need to modify the AMR. When an application program invokes this service, the operating system would set the UAMOR to the non-zero value appropriate to the access authorities (load and/or store, for one or more key values) that the application program is allowed to modify, and thereafter would save and restore the AMR (and preserve the UAMOR) for this application program. (Having the UAMOR contain all 0s does not prevent an "AMR-unaware" program from reading the AMR, but inadvertently reading of the AMR is likely to be much less harmful than inadvertently modifying it.)

(For partitions that run in a compatibility mode corresponding to a version of the architecture that precedes Version 2.06, the PCR provides sufficient protection to application programs.)

### Programming Note

Initialization of the UAMOR to all 0s, by the hypervisor before dispatching a partition for the first time, as described in the preceding Programming Note, permits operating systems (in partitions that run in a compatibility mode corresponding to Version 2.06 of the architecture or a subsequent version) to migrate gradually to supporting problem state access to the AMR — specifically, to avoid having to be changed immediately to modify the UAMOR and to save the AMR contents when an interrupt occurs from problem state. Relatedly, having the UAMOR contain all 0s while an application program is running protects old application programs that are "AMR-unaware". In the absence of programming errors, such application programs would not attempt to read or modify the AMR. However, having the UAMOR contain all 0s protects such programs against modifying the AMR inadvertently.

Permitting an "AMR-unaware" application program to modify the AMR (inadvertently) is potentially harmful for the obvious reasons. (The program might set to 1 an AMR bit corresponding to accesses that are necessary in order for the program to work correctly.) Moreover, even for an operating system that includes support for problem state modification of the AMR, having the UAMOR contain all 0s allows the operating system to avoid saving and restoring the AMR for "AMR-unaware" application programs. Such an operating system would provide a system service program that allows an application program to declare itself to be "AMR-aware" — i.e., potentially to need to modify the AMR. When an application program invokes this service, the operating system would set the UAMOR to the non-zero value appropriate to the access authorities (load and/or store, for one or more key values) that the application program is allowed to modify, and thereafter would save and restore the AMR (and preserve the UAMOR) for this application program. (Having the UAMOR contain all 0s does not prevent an "AMR-unaware" program from reading the AMR, but inadvertently reading of the AMR is likely to be much less harmful than inadvertently modifying it.)

(For partitions that run in a compatibility mode corresponding to a version of the architecture that precedes Version 2.06, the PCR provides sufficient protection to application programs.)
Kₚ and Kₛ, the supervisor (privileged) state and problem state storage key bits in the SLB entry used to translate the effective address.

PP, page protection bits 0:2 in the Page Table Entry used to translate the effective address.

- For instruction fetches only:
  - the N (No-execute) value used for the access (see Sections 5.7.6.1 and 5.7.7.3)
  - PTE_INDEX, the G (Guarded) bit in the Page Table Entry used to translate the effective address

Using the above values, the following rules are applied.

1. For an instruction fetch, the access is not permitted if the N value is 1 or if PTE_INDEX = 1.

2. For any access except an instruction fetch that is not permitted by rule 1, a “Key” value is computed using the following formula:

$$\text{Key} = (K_p \& \text{MSR PR}) | (K_s \& \neg \text{MSR PR})$$

Using the computed Key, Figure 32 is applied. An instruction fetch is permitted for any entry in the figure except “no access”. A load is permitted for any entry except “no access”. A store is permitted only for entries with “read/write”.

Using the above values, the following rules are applied.

1. If MSR_HV = 0 and VPM₀ = 1, access authority is determined as described in Section 5.7.3.4.

2. If MSR_HV = 1 or VPM₀ = 0, Figure 33 is applied. The access is permitted for any entry in the figure except “no access”.

¹ If the effective address for the access is less than the value specified by the RMLS, the access authority is read/write; otherwise the access is not permitted.

Figure 33. Protection states, address translation disabled

Programming Note

The comparison described in note 1 in Figure 33 ignores bits 0:3 of the effective address and may ignore bits 4:63-m; see Section 5.7.3.

### 5.7.9.3 Basic Storage Protection, Address Translation Disabled

When address translation is disabled, the Basic Storage Protection mechanism is controlled by the following (see Chapter 2 and Section 5.7.3, “Real And Virtual Real Addressing Modes”).

- MSR_HV, which (when MSR_PP = 0) distinguishes between hypervisor state and privileged but non-hypervisor state
- VPM₀, which distinguishes between real addressing mode and virtual real addressing mode
- RMLS, which specifies the real mode limit value

5.8 Storage Control Attributes

This section describes aspects of the storage control attributes that are relevant only to privileged software programmers. The rest of the description of storage control attributes may be found in Section 1.6 of Book II and subsections.

5.8.1 Guarded Storage

Storage is said to be "well-behaved" if the corresponding real storage exists and is not defective, and if the effects of a single access to it are indistinguishable from the effects of multiple identical accesses to it. Data and instructions can be fetched out-of-order from well-behaved storage without causing undesired side effects.

Storage is said to be Guarded if any of the following conditions is satisfied.

- MSR bit IR or DR is 1 for instruction fetches or data accesses respectively, and the G bit is 1 in the relevant Page Table Entry.
- MSR bit IR or DR is 0 for instruction fetches or data accesses respectively, MSR_{HV}=1, and the storage is outside the range(s) specified by the Hypervisor Real Mode Storage Control facility (see Section 5.7.3.3.1).

In general, storage that is not well-behaved should be Guarded. Because such storage may represent a control register on an I/O device or may include locations that do not exist, an out-of-order access to such storage may cause an I/O device to perform unintended operations or may result in a Machine Check.

The following rules apply to in-order execution of Load and Store instructions for which the first byte of the storage operand is in storage that is both Caching Inhibited and Guarded.

- Load or Store instruction that causes an atomic access
  - If any portion of the storage operand has been accessed and an External, Decrementer, Hypervisor Decrementer, Performance Monitor, or Imprecise mode Floating-Point Enabled exception is pending, the instruction completes before the interrupt occurs.
- Load or Store instruction that causes an Alignment exception, or that causes a [Hypervisor] Data Storage exception for reasons other than Data Address Watchpoint match.

The portion of the storage operand that is in Caching Inhibited and Guarded storage is not accessed.

5.8.2 Storage Control Bits

When address translation is enabled, each storage access is performed under the control of the Page Table Entry used to translate the effective address. Each Page Table Entry contains storage control bits that specify the presence or absence of the corre-
sponding storage control for all accesses translated by the entry as shown in Figure 34.

<table>

<td>0 - not Memory Coherence Required</td>
</tr>
<tr>
<td>G</td>
<td>0 - not Guarded</td>
</tr>
</tbody>
</table>

1 Support for the 1 value of the W bit is optional. Implementations that do not support the 1 value treat the bit as reserved and assume its value to be 0.

2 [Category: Memory Coherence] Support for the 0 value of the M bit is optional, implementations that do not support the 0 value assume the value of the bit to be 1, and may either preserve the value of the bit or write it as 1.

3 [Category: SAO] The combination $\text{WIMG} = \text{0b1110}$ has behavior unrelated to the meanings of the individual bits. See see Section 5.8.2.1, “Storage Control Bit Restrictions” for additional information.

Figure 34. Storage control bits

When address translation is enabled, instructions are not fetched from storage for which the G bit in the Page Table Entry is set to 1; see Section 5.7.9.

When address translation is disabled, the storage control attributes are implicit; see Section 5.7.3.3.

In Sections 5.8.2.1 and 5.8.2.2, “access” includes accesses that are performed out-of-order, and references to $W$, $I$, $M$, and $G$ bits include the values of those bits that are implied when address translation is disabled.

Programming Note

In a system consisting of only a single-threaded processor which has caches, correct coherent execution does not require storage to be accessed as Memory Coherence Required, and accessing storage as not Memory Coherence Required may give better performance.

5.8.2.1 Storage Control Bit Restrictions

All combinations of $W$, $I$, $M$, and $G$ values are permitted except those for which both $W$ and $I$ are 1 and $MI/G \neq \text{0b10}$.

The combination $\text{WIMG} = \text{0b1110}$ is used to identify the Strong Access Ordering (SAO) storage attribute (see Section 1.7.1, “Storage Access Ordering”, in Book II). Because this attribute is not intended for general purpose programming, it is provided only for a single combination of the attributes normally identified using the WIMG bits. That combination would normally be indicated by $\text{WIMG} = \text{0b0010}$.

References to Caching Inhibited storage (or storage with $I=1$) elsewhere in the Power ISA have no application to SAO storage or its WIMG encoding, despite the encoding using $I=1$. Conversely, references to storage that is not Caching Inhibited (or storage with $I=0$) apply to SAO storage or its WIMG encoding. References to Write Through Required storage (or storage with $W=1$) elsewhere in the Power ISA have no application to SAO storage or its WIMG encoding, despite the fact that the encoding uses $W=1$. Conversely, references to storage that is not Write Through Required (or storage with $W=0$) apply to SAO storage or its WIMG encoding.

If a given real page is accessed concurrently as SAO storage and as non-SAO storage, the result may be characteristic of the weakly consistent model.

Programming Note

If an application program requests both the Write Through Required and the Caching Inhibited attributes for a given storage location, the operating system should set the I bit to 1 and the W bit to 0. For implementations that support the SAO category, the operating system should provide a means by which application programs can request SAO storage, in order to avoid confusion with the preceding guideline (since SAO is encoded using $WI=\text{0b11}$).

At any given time, the value of the W bit must be the same for all accesses to a given real page.

At any given time, the value of the I bit must be the same for all accesses to a given real page.

5.8.2.2 Altering the Storage Control Bits

When changing the value of the W bit for a given real page from 0 to 1, software must ensure that no thread modifies any location in the page until after all copies of locations in the page that are considered to be modified in the data caches have been copied to main storage using $\text{dcbst}$ or $\text{dcbf}[l]$.

When changing the value of the I bit for a given real page from 0 to 1, software must set the I bit to 1 and then flush all copies of locations in the page from the caches using $\text{dcbf}[l]$ and $\text{idcbi}$ before permitting any other accesses to the page. Note that similar cache management is required before using the Fixed-Point Load and Store Caching Inhibited instructions to
access storage that has formerly been cached. (See Section 4.4.1 on page 875.)

--- Programming Note ---

The storage control bit alterations described above are examples of cases in which the directives for application of statements about the W and I bits to SAO given in the third paragraph of the preceding subsection must be applied. A transition from the typical WIMG=0b0010 for ordinary storage to WIMG=0b1110 for SAO storage does not require the flush described above because both WIMG combinations indicate storage that is not Caching Inhibited.

--- Programming Note ---

It is recommended that \texttt{dcbf} be used, rather than \texttt{dcbfl}, when changing the value of the I or W bit from 0 to 1. (\texttt{dcbfl} would have to be executed on all threads for which the contents of the data cache may be inconsistent with the new value of the bit, whereas, if the M bit for the page is 1, \texttt{dcbf} need be executed on only one thread in the system.)

When changing the value of the M bit for a given real page, software must ensure that all data caches are consistent with main storage. The actions required to do this are system-dependent.

--- Programming Note ---

For example, when changing the M bit in some directory-based systems, software may be required to execute \texttt{dcbf} on each thread to flush all storage locations accessed with the old M value before permitting the locations to be accessed with the new M value.

Additional requirements for changing the storage control bits in the Page Table are given in Section 5.10.
5.9 Storage Control Instructions

5.9.1 Cache Management Instructions

This section describes aspects of cache management that are relevant only to privileged software programmers.

For a `dcbz` instruction that causes the target block to be newly established in the data cache without being fetched from main storage, the hardware need not verify that the associated real address is valid. The existence of a data cache block that is associated with an invalid real address (see Section 5.6) can cause a delayed Machine Check interrupt or a delayed Checkstop.

Each implementation provides an efficient means by which software can ensure that all blocks that are considered to be modified in the data cache have been copied to main storage before the thread enters any power conserving mode in which data cache contents are not maintained.

5.9.2 Synchronize Instruction

The `Synchronize` instruction is described in Section 4.4.3 of Book II, but only at the level required by an application programmer. This section describes properties of the instruction that are relevant only to operating system and hypervisor software programmers.

When L=0, the `sync` instruction also provides an ordering function for the operations caused by the `Message Send` instruction and previous `Stores`. The stores must be performed with respect to the processor receiving the message prior to any access caused by or associated with any instruction executed after the corresponding interrupt occurs.

When L=1, the `sync` instruction provides an ordering function for the operations caused by the `Message Send` instruction and previous `Stores` for which the specified storage location is in storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited. The stores must be performed with respect to the processor receiving the message prior to any access caused by or associated with any instruction executed after the corresponding interrupt occurs.

Another variant of the `Synchronize` instruction is described below. It is designated the Page Table Entry Synchronize instruction, and is specified by the extended mnemonic `ptesync` (equivalent to `sync` with L=2).

The `ptesync` instruction has all of the properties of `sync` with L=0 and also the following additional properties.

- The memory barrier created by the `ptesync` instruction provides an ordering function for the storage accesses associated with all instructions that are executed by the thread executing the `ptesync` instruction and, as elements of set A, for all Reference and Change bit updates associated with additional address translations that were performed, by the thread executing the `ptesync` instruction, before the `ptesync` instruction is executed. The applicable pairs are all pairs \(a_i,b_j\) in which \(b_j\) is a data access and \(a_i\) is not an instruction fetch.

- The `ptesync` instruction causes all Reference and Change bit updates associated with address translations that were performed, by the thread executing the `ptesync` instruction, before the `ptesync` instruction is executed, to be performed with respect to that thread before the `ptesync` instruction's memory barrier is created.

- The `ptesync` instruction provides an ordering function for all stores to the Page Table caused by `Store` instructions preceding the `ptesync` instruction with respect to searches of the Page Table that are performed, by the thread executing the `ptesync` instruction, after the `ptesync` instruction completes. Executing a `ptesync` instruction ensures that all such stores will be performed, with respect to the thread executing the `ptesync` instruction, before any implicit accesses to the affected Page Table Entries, by such Page Table searches, are performed with respect to that thread.

- In conjunction with the `tlbie` and `tlbsync` instructions, the `ptesync` instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the `tlbsync` instruction description on page 934.
5.9.3 Lookaside Buffer Management

All implementations have a Segment Lookaside Buffer (SLB). For performance reasons, most implementations also have implementation-specific lookaside information that is used in address translation. This lookaside information may be: a Translation Lookaside Buffer (TLB) which is a cache of recently used Page Table Entries (PTEs); a cache of recently used translations of effective addresses to real addresses; etc.; or any combination of these. Lookaside information, including the SLB, is managed using the instructions described in the subsections of this section.

Lookaside information derived from PTEs is not necessarily kept consistent with the Page Table. When software alters the contents of a PTE, in general it must also invalidate all corresponding implementation-specific lookaside information; exceptions to this rule are described in Section 5.10.1.2.

The effects of the `slbie`, `slbia`, and TLB Management instructions on address translations, as specified in Sections 5.9.3.1 and 5.9.3.3 for the SLB and TLB respectively, apply to all implementation-specific lookaside information that is used in address translation. Unless otherwise stated or obvious from context, references to SLB entry invalidation and TLB entry invalidation elsewhere in the Books apply also to all implementation-specific lookaside information that is derived from SLB entries and PTEs respectively.

The `tlbia` instruction is optional. However, all implementations provide a means by which software can invalidate all implementation-specific lookaside information that is derived from PTEs.

Implementation-specific lookaside information that contains translations of effective addresses to real addresses may include “translations” that apply in real addressing mode. Because such “translations” are affected by the contents of the LPCR, RMOR, and HRMOR, when software alters the contents of these registers it must also invalidate the corresponding implementation-specific lookaside information. Software can invalidate all such lookaside information by using the `slbia` instruction with IH=0b000. However, performance is likely to be better if other, appropriate, IH values are used to limit the amount of lookaside information that invalidated.

All implementations that have such lookaside information provide a means by which software can invalidate all such lookaside information.

For simplicity, elsewhere in the Books it is assumed that the TLB exists.

--- Programming Note ---

Because the instructions used to manage implementation-specific lookaside information that is derived from PTEs may be changed in a future version of the architecture, it is recommended that software “encapsulate” uses of the TLB Management instructions into subroutines.

--- Programming Note ---

The function of all the instructions described in Sections 5.9.3.1 - 5.9.3.3 is independent of whether address translation is enabled or disabled.

For a discussion of software synchronization requirements when invalidating SLB and TLB entries, see Chapter 12.

5.9.3.1 SLB Management Instructions

--- Programming Note ---

Accesses to a given SLB entry caused by the instructions described in this section obey the sequential execution model with respect to the contents of the entry and with respect to data dependencies on those contents. That is, if an instruction sequence contains two or more of these instructions, when the sequence has completed, the final contents of the SLB entry and of General Purpose Registers is as if the instructions had been executed in program order.

However, software synchronization is required in order to ensure that any alterations of the entry take effect correctly with respect to address translation; see Chapter 12.
Changes to the segment mappings in the presence of active transactions may compromise transactional semantics if the transaction has accessed a segment that is assigned a new VSID. Consequently, when modifying segment mappings, it is the responsibility of the OS or hypervisor to ensure that any transaction that may have touched the modified segment is terminated, using a `tabort` or `treclaim` instruction.

---

**Programming Note**

Changes to the segment mappings in the presence of active transactions may compromise transactional semantics if the transaction has accessed a segment that is assigned a new VSID. Consequently, when modifying segment mappings, it is the responsibility of the OS or hypervisor to ensure that any transaction that may have touched the modified segment is terminated, using a `tabort` or `treclaim` instruction.

---

### SLB Invalidate Entry

<table>
<thead>
<tr>
<th>slbie</th>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td></td>
</tr>
<tr>
<td>6</td>
<td></td>
</tr>
<tr>
<td>11</td>
<td></td>
</tr>
<tr>
<td>16</td>
<td>434</td>
</tr>
</tbody>
</table>

\[
ea_{0:35} \leftarrow \langle RB \rangle_{0:35}
\]

if, for SLB entry that translates
or most recently translated ea,
entry_class = \langle RB \rangle_{36}
entry_seg_size = size specified in \langle RB \rangle_{37:38}
then for SLB entry (if any) that translates ea
SLBE_V \leftarrow 0
all other fields of SLBE \leftarrow undefined
else
s \leftarrow \log_{2}(\text{entry_seg_size})
esid \leftarrow \langle RB \rangle_{0:63} - s
u \leftarrow undefined 1-bit value
if u then
if an SLB entry translates esid
SLBE_V \leftarrow 0
all other fields of SLBE \leftarrow undefined

Let the Effective Address (EA) be any EA for which \(EA_{0:35} = \langle RB \rangle_{0:35}\). Let the class be \(\langle RB \rangle_{36}\). Let the segment size be equal to the segment size specified in \(\langle RB \rangle_{37:38}\); the allowed values of \(\langle RB \rangle_{37:38}\), and the correspondence between the values and the segment size, are the same as for the B field in the SLBE (see Figure 21 on page 897).

The class value and segment size must be the same as the class value and segment size in the SLB entry that translates the EA, or the values that were in the SLB entry that most recently translated the EA if the translation is no longer in the SLB; if these values are not the same, it is implementation-dependent whether the SLB entry (or implementation-dependent translation information) that translates the EA is invalidated, and the next paragraph need not apply.

If the SLB contains only a single entry that translates the EA, then that is the only SLB entry that is invalidated, except that it is implementation-dependent whether an implementation-specific lookaside entry for a real mode address “translation” is invalidated. If the SLB contains more than one such entry, then zero or more such entries are invalidated, and similarly for any implementation-specific lookaside information used in address translation; additionally, a machine check may occur.

SLB entries are invalidated by setting the V bit in the entry to 0, and the remaining fields of the entry are set to undefined values.

The hardware ignores the contents of RB listed below and software must set them to 0s.

- \(\langle RB \rangle_{37}\)
- \(\langle RB \rangle_{39}\)
- \(\langle RB \rangle_{40:63}\)
- If \(s = 40\), \(\langle RB \rangle_{24:35}\)
If this instruction is executed in 32-bit mode, \((RB)_{0:31}\) must be zeros.

This instruction is privileged.

**Special Registers Altered:**

None

---

**Programming Note**

*slbie* does not affect SLBs on other threads.

---

**Programming Note**

The reason the class value specified by *slbie* must be the same as the Class value that is or was in the relevant SLB entry is that the hardware may use these values to optimize invalidation of implementation-specific lookaside information used in address translation. If the value specified by *slbie* differs from the value that is or was in the relevant SLB entry, these optimizations may produce incorrect results. (An example of implementation-specific address translation lookaside information is the set of recently used translations of effective addresses to real addresses that some implementations maintain in an Effective to Real Address Translation (ERAT) lookaside buffer.)

When switching tasks in certain cases, it may be advantageous to preserve some implementation-specific lookaside entries while invalidating others. The IH=0b001 invalidation hint of the *slbia* instruction can be used for this purpose if SLB class values are appropriately assigned, i.e., a class value of 0 gives the hint that the entry should be preserved and a class value of 1 indicates the entry must be invalidated. Also, it is advantageous to assign a class value of 1 to entries that need to be invalidated via an *slbie* instruction while preserving implementation-specific lookaside entries that are not derived from an SLB entry since such entries are assigned a class value of 0.

The *Move To Segment Register* instructions (see Section 5.9.3.2.1) create SLB entries in which the Class value is 0.

---

**Programming Note**

The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

---

### SLB Invalidate All

<table>
<thead>
<tr>
<th>X-form</th>
</tr>
</thead>
<tbody>
<tr>
<td>slbia</td>
</tr>
</tbody>
</table>

For each SLB entry except SLB entry 0

\[
\text{SLBE}_v \leftarrow 0
\]

all other fields of SLBE \leftarrow undefined

For all SLB entries except SLB entry 0, the V bit in the entry is set to 0, making the entry invalid, and the remaining fields of the entry are set to undefined values. SLB entry 0 is not altered.

On implementations that have implementation-specific lookaside information for effective to real address translations, the IH field provides a hint that can be used to invalidate entries selectively in such lookaside information. The defined values for IH are as follows.

- 0b000 All such implementation-specific lookaside information is invalidated. (This value is not a hint.)
- 0b001 Preserve such implementation-specific lookaside information having a Class value of 0.
- 0b010 Preserve such implementation-specific lookaside information created when MSRIR/DR=0.
- 0b110 Preserve such implementation-specific lookaside information created when MSRIR/DR=0.

All other IH values are reserved. If the IH field contains a reserved value, the hint provided by the IH field is undefined.

Implementation specific lookaside information for which preservation is not requested is invalidated. Implementation specific lookaside information for which preservation is requested may be invalidated.

When IH=0b000, execution of this instruction has the side effect of clearing the storage access history associated with the Hypervisor Real Mode Storage Control facility. See Section 5.7.3.3.1, “Hypervisor Real Mode Storage Control” for more details.

This instruction is privileged.

**Special Registers Altered:**

None

---

**Programming Note**

*slbia* does not affect SLBs on other threads.
Programming Note

If `slbia` is executed when instruction address translation is enabled, software can ensure that attempting to fetch the instruction following the `slbia` does not cause an Instruction Segment interrupt by placing the `slbia` and the subsequent instruction in the effective segment mapped by SLB entry 0. (The preceding assumes that no other interrupts occur between executing the `slbia` and executing the subsequent instruction.)

If it is desired to invalidate the entire SLB and all associated implementation-specific lookaside information, the following sequence can be used. The sequence assumes that address translation is disabled.

```
li r0,0
slbmt r0,r0 # clear SLBE 0
slbia 0b0000 # invalidate all other
# SLBEs, and all ERATEs
```

Programming Note

The defined values for IH are as follows.

<table>
<thead>
<tr>
<th>0b000</th>
<th>All ERAT entries are invalidated. (This value is not a hint.) This value should be used by the hypervisor when relocating itself (i.e. when modifying the HRMOR) or when reconfiguring real storage.</th>
</tr>
</thead>
<tbody>
<tr>
<td>0b001</td>
<td>Preserve ERAT entries with a Class value of 0. This value should be used by an operating system when switching tasks in certain cases; for example, if SLBE&lt;sub&gt;C&lt;/sub&gt;=0 is used for SLB translations shared between the tasks.</td>
</tr>
<tr>
<td>0b010</td>
<td>Preserve ERAT entries created when MSR&lt;sub&gt;IR&lt;/sub&gt;/DR=0. This value should generally be used by an operating system when switching tasks.</td>
</tr>
<tr>
<td>0b110</td>
<td>Preserve ERAT entries created when MSR&lt;sub&gt;HV&lt;/sub&gt;=1 and MSR&lt;sub&gt;IR&lt;/sub&gt;/DR=0. This value should be used by the hypervisor when switching partitions.</td>
</tr>
</tbody>
</table>

**SLB Move To Entry**

<table>
<thead>
<tr>
<th>X-form</th>
<th>( \text{slbmt} )</th>
<th>RS, RB</th>
</tr>
</thead>

<th>V</th>
<th>0s</th>
<th>index</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>36</td>
<td>37</td>
<td>52</td>
</tr>
</tbody>
</table>

**Programming Note**

`slbia` serves as both a basic and an extended mnemonic. The Assembler will recognize an `slbia` mnemonic with one operand as the basic form, and an `slbia` mnemonic with no operand as the extended form. In the extended form the IH operand is omitted and assumed to be 0.

**Programming Note**

If `slbia` is executed when instruction address translation is enabled, software can ensure that attempting to fetch the instruction following the `slbia` does not cause an Instruction Segment interrupt by placing the `slbia` and the subsequent instruction in the effective segment mapped by SLB entry 0. (The preceding assumes that no other interrupts occur between executing the `slbia` and executing the subsequent instruction.)

If it is desired to invalidate the entire SLB and all associated implementation-specific lookaside information, the following sequence can be used. The sequence assumes that address translation is disabled.

```
li r0,0
slbmt r0,r0 # clear SLBE 0
slbia 0b0000 # invalidate all other
# SLBEs, and all ERATEs
```

**Figure 35. GPR contents for slbmt**

On implementations that support a virtual address size of only \( n \) bits, \( n < 78 \), (RS)<sub>2:79-n</sub> must be zeros.

(RS)<sub>57</sub> and (RS)<sub>60:63</sub> are ignored by the hardware.

High-order bits of (RB)<sub>52:63</sub> that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

If this instruction is executed in 32-bit mode, (RB)<sub>0:31</sub> must be zeros (i.e., the ESID must be in the range 0:15).

This instruction cannot be used to invalidate the translation contained in an SLB entry.

This instruction is privileged.

**Special Registers Altered:** None

**SLB Find Entry ESID**

\[ \text{slbfee RT, RB} \]

The SLB is searched for an entry that matches the effective address specified by register RB. The search is performed as if it were being performed for purposes of address translation. That is, in order for a given entry to satisfy the search, the entry must be valid (V=1), and \( (RB)_{63-s} \) must equal \( \text{SLBE}[	ext{ESID}_{63-s}] \) (where \( 2^s \) is the segment size selected by the B field in the entry). If exactly one matching entry is found, the contents of the B, VSID, \( K_p, K_p, N, L, C, \) and LP fields of the entry are placed into register RT. If no matching entry is found, register RT is set to 0. If more than one matching entry is found, either one of the matching entries is used, as if it were the only matching entry, or a Machine Check occurs. If a Machine Check occurs, register RT, and CR Field 0 are set to undefined values, and the description below of how this register and this field is set does not apply.

The contents of registers RT and RB are interpreted as shown in Figure 38.

5.9.3.2 Bridge to SLB Architecture [Category:Server.Phased-Out]

The facility described in this section can be used to ease the transition to the current Power ISA software-managed Segment Lookaside Buffer (SLB) architecture, from the Segment Register architecture provided by 32-bit PowerPC implementations. A complete description of the Segment Register architecture may be found in “Segmented Address Translation, 32-Bit Implementations,” Section 4.5, Book III of Version 1.10 of the PowerPC architecture, referenced in the introduction to this architecture.

The facility permits the operating system to continue to use the 32-bit PowerPC implementation’s Segment Register Manipulation instructions.

5.9.3.2.1 Segment Register Manipulation Instructions

The instructions described in this section -- mtssr, mtssrin, msfr, and mfsrin -- allow software to associate effective segments 0 through 15 with any of virtual segments 0 through 227-1. SLB entries 0:15 serve as virtual Segment Registers, with SLB entry i used to emulate Segment Register i. The mtssr and mtssrin instructions move 32 bits from a selected GPR to a selected SLB entry. The msfr and mfsrin instructions move 32 bits from a selected SLB entry to a selected GPR.

The contents of the GPRs used by the instructions described in this section are shown in Figure 39. Fields shown as zeros must be zero for the Move To Segment Register instructions. Fields shown as hyphens are ignored. Fields shown as periods are ignored by the Move To Segment Register instructions and set to undefined values by the Move From Segment Register instructions. Fields shown as colons are ignored by the Move To Segment Register instructions and set to undefined values by the Move From Segment Register instructions.

Figure 39. GPR contents for mtssr, mtssrin, msfr, and mfsrin

The “Segment Register” format used by the instructions described in this section corresponds to the low-order 32 bits of RS and RT shown in the figure. This format is essentially the same as that for the Segment Registers of 32-bit PowerPC implementations. The only differences are the following.

- Bit 36 corresponds to a reserved bit in Segment Registers. Software must supply 0 for the bit because it corresponds to the L bit in SLB entries, and large pages are not supported for SLB entries created by the Move To Segment Register instructions.
- VSID bits 23:25 correspond to reserved bits in Segment Registers. Software can use these extra VSID bits to create VSIDs that are larger than those supported by the Segment Register Manipulation instructions of 32-bit PowerPC implementations.

Bit 32 of RS and RT corresponds to the T (direct-store) bit of early 32-bit PowerPC implementations. No corresponding bit exists in SLB entries.

Programming Note

The Programming Note in the introduction to Section 5.9.3.1 applies also to the Segment Register Manipulation instructions described in this section, and to any combination of the instructions described in the two sections, except as specified below for msfr and mfsrin.

The requirement that the SLB contain at most one entry that translates a given effective address (see Section 5.7.6.1) applies to SLB entries created by mtssr and mtssrin. This requirement is satisfied naturally if only mtssr and mtssrin are used to create SLB entries for a given ESID, because for these instructions the association between SLB entries and ESID values is fixed (SLB entry i is used for ESID i). However, care must be taken if slbmt is also used to create SLB entries for the ESID, because for slbmt the association between SLB entries and ESID values is specified by software.
Move To Segment Register X-form

mtsr SR,RS

The SLB entry specified by SR is loaded from register RS, as follows.

5.9.3.3 TLB Management Instructions

**Programming Note**

Changes to the page table in the presence of active transactions may compromise transactional semantics if a page accessed by a translation is remapped within the lifetime of the transaction. Through the use of a *tlbie* instruction to the unmapped page, an operating system or hypervisor can ensure that any transaction that has touched the affected page is terminated.

Changes to local translation lookaside buffers, through the *tlbia* and *tlbiel* instructions have no effect on transactions. Consequently, if these instructions are used to invalidate TLB entries after the unmapping of a page, it is the responsibility of the OS or hypervisor to ensure that any transaction that may have touched the modified page is terminated, using a tabort. or treclaim instruction.

Changes to local translation lookaside buffers, through the use of the *tlbie* instruction to the unmapped page, an operating system or hypervisor can ensure that any transaction that has touched the affected page is terminated.

The operation performed by this instruction is based on the contents of registers RS and RB. The contents of these registers are shown below, where L is (RB)63.

**RS**:

<table>
<thead>
<tr>
<th>0s</th>
<th>LPID</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>44</td>
<td>52</td>
<td>54</td>
<td>56</td>
<td>63</td>
</tr>
</tbody>
</table>

**RS** contains an LPID value. The supported (RS)32:63 values are the same as the LPID values supported in LPIDR. RS0:31 must contain zeros and are ignored by the hardware.

If the L field in RB contains 0, the base page size is 4 KB and RB56:58 (AP - Actual Page size field) must be set to the SLBE_LILP encoding for the page size corresponding to the actual page size specified by the PTE that was used to create the TLB entry to be invalidated. Thus, b is equal to 12 and p is equal to log₂ (actual page size specified by (RB)56:58). The Abbreviated Virtual Address (AVA) field in register RB must contain bits 14:65 of the virtual address translated by the TLB entry to be invalidated. Variable i is equal to 51.

If the L field in RB contains 1, the following rules apply.

- The base page size and actual page size are specified in the LP field in register RB, where the relationship between (RB)44:51 (LP - Large Page size selector field) and the base page size and actual page size is the same as the relationship between PTE_LP and the base page size and actual page size, except for the "r" bits (see Section 5.7.7.1 on page 900 and Figure 25 on page 901). Thus, b is equal to log₂ (base page size specified by (RB)44:51) and p is equal to log₂ (actual page size specified by (RB)44:51). Specifically, (RB)44+c:51 must be equal to the contents of bits c:7 of the LP field of the PTE that was used to create the TLB entry to be invalidated, where c is the maximum of 0 and (20-p).
- Variable i is the larger of (63-p) and the value that is the smaller of 43 and (63-b). (RB)log₂ contains bits 14:(i+14) of the virtual address translated by the TLB entry to be invalidated. If b>20, RB64-b:43
may contain any value and are ignored by the hardware.

- If \( b < 20 \), \((RB)_{56:75-b}\) must contain bits \(58:77-b\) of the virtual address translated by the TLB to be invalidated, and other bits in \((RB)_{56:62}\) may contain any value and are ignored by the hardware.

- If \( b \geq 20 \), \((RB)_{56:62}\) (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.

Let the segment size be equal to the segment size specified in \((RB)_{54:55}\) (B field). The contents of \(RB_{54:55}\) must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

\(RB_{52:53}\) and \(RB_{59:62}\) (when \((RB)_{63} = 0\)) must contain zeros and are ignored by the hardware.
All TLB entries on all threads that have all of the following properties are made invalid.

- The entry translates a virtual address for which all the following are true.
  - $V_{A14:14+i}$ is equal to $(RB)_{0:i}$.
  - $L=0$ or $b \geq 20$ or, if $L=1$ and $b=20$, $V_{A58:77-b}$ is equal to $(RB)_{56:75-b}$.
  - The segment size of the entry is the same as the segment size specified in $(RB)_{54:55}$.
- Either of the following is true:
  - The L field in RB is 0, the base page size of the entry is 4 KB, and the actual page size of the entry matches the actual page size specified in $(RB)_{56:58}$.
  - The L field in RB is 1, the base page size of the entry matches the base page size specified in $(RB)_{44:51}$, and the actual page size of the entry matches the actual page size specified in $(RB)_{54:55}$.
- Either of the following is true:
  - The implementation’s TLB entries contain LPID values and TLBELLPID = $(RS)_{32:63}$.
  - The implementation’s TLB entries do not contain LPID values, and LPIDR LPID = $(RS)_{32:63}$. The LPIDR used for this comparison is in the same thread as the TLB entry being tested.

If the implementation’s TLB entries contain LPID values, additional TLB entries may also be made invalid if those TLB entries contain an LPID that matches $(RS)_{32:63}$. If the implementation’s TLB entries do not contain LPID values, additional TLB entries may also be made invalid on any thread that is in the partition specified by $(RS)_{32:63}$.

MSR$_{SF}$ must be 1 when this instruction is executed; otherwise the results are undefined.

If the value specified in RS$_{32:63}$, RB$_{54:55}$, RB$_{56:58}$ (when RB$_{63}=0$), or RB$_{44:51}$ (when RB$_{63}=1$) is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

The operation performed by this instruction is ordered by the eieio (or sync or ptesync) instruction with respect to a subsequent tlbsync instruction executed by the thread executing the tlbie instruction. The operations caused by tlbie and tlbsync are ordered by eieio as a fourth set of operations, which is independent of the other three sets that eieio orders.

This instruction is hypervisor privileged.

See Section 5.10, “Page Table Update Synchronization Requirements” for a description of other requirements associated with the use of this instruction.

Special Registers Altered:

- None

---

**Programming Note**

For tlbie[] instructions in which $(RB)_{63}=0$, the AP value in RB is provided to make it easier for the hardware to locate address translations, in lookaside buffers, corresponding to the address translation being invalidated.

For tlbie[] instructions the AP specification is not binary compatible with versions of the architecture that precede Version 2.06. As an example, for an actual page size of 64 KB AP=0b101, whereas software written for an implementation that complies with a version of the architecture that precedes V. 2.06 would have AP=100 since AP was a 1 bit value followed by Os in RB$_{57:58}$. If binary compatibility is important, for a 64 KB page software can use AP=0b101 on these earlier implementations since these implementations were required to ignore RB$_{57:58}$.

For tlbie[] instructions the AVA and AVAL fields in RB contain different VA bits from those in PTEAVA.

<td>54</td>
<td>56</td>
<td>59</td>
<td>63</td>
</tr>
</tbody>
</table>

The Invalidation Selector (IS) field in RB has three defined values (0b00, 0b10, and 0b11). The IS value of 0b01 is reserved and is treated in the same manner as the corresponding case for instruction fields (see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” on page 5 in Book I).

**Engineering Note**

**IS field in RB contains 0b00**

If the L field in RB contains 0, the base page size is 4 KB and RB56:58 (AP - Actual Page size field) must be set to the SLBE_LLP encoding for the page size corresponding to the actual page size specified by the PTE that was used to create the TLB entry to be invalidated. Thus, b is equal to 12 and p is equal to \( \log_2 \) (actual page size specified by RB56:58). The Abbreviated Virtual Address (AVA) field in register RB must contain bits 14:65 of the virtual address translated by the TLB entry to be invalidated. Variable i is equal to 51.

If the L field in RB contains 1, the following rules apply.

- The base page size and actual page size are specified in the LP field in register RB, where the relationship between (RB)44:51 (LP - Large Page size selector field) and the base page size and actual page size is the same as the relationship between PTE_LP and the base page size and actual page size, except for the “r” bits (see Section 5.7.7.1 on page 900 and Figure 25 on page 901). Thus, b is equal to \( \log_2 \) (base page size specified by RB44:51) and p is equal to \( \log_2 \) (actual page size specified by RB44:51). Specifically, (RB)44+c:51 must be equal to the contents of bits c:7 of the LP field of the PTE that was used to create the TLB entry to be invalidated, where c is the maximum of 0 and (20-p).
- Variable i is the larger of (63-p) and the value that is the smaller of 43 and (63-b). (RB)0:i must contain bits 14:(i +14) of the virtual address translated by the TLB to be invalidated, and other bits in (RB)56:62 may...
contain any value and are ignored by the hardware.
- If \( b \geq 20 \), \((RB)_{56:62}\) (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.

Let the segment size be equal to the segment size specified in \((RB)_{54:55}\) (B field). The contents of \(RB_{54:55}\) must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

Let the segment size be equal to the segment size specified in \((RB)_{54:55}\) (B field). The contents of \(RB_{54:55}\) must be the same as the contents of PTEB used to create the TLB entry to be invalidated.

All TLB entries that have all of the following properties are made invalid on the thread executing the \texttt{tlbiel} instruction.
- The entry translates a virtual address for which all the following are true.
  - \( VA_{14:14+i} \) is equal to \((RB)_{0:i}\).
  - \( L=0 \) or \( b \geq 20 \) or, if \( L=1 \) and \( b < 20 \), \( VA_{58:77-b} \) is equal to \((RB)_{56:75-b}\).
- The segment size of the entry is the same as the segment size specified in \((RB)_{54:55}\).
- Either of the following is true:
  - The L field in RB is 0, the base page size of the entry is 4 KB, and the actual page size of the entry matches the actual page size specified in \((RB)_{56:58}\).
  - The L field in RB is 1, the base page size of the entry matches the base page size specified in \((RB)_{44:51}\), and the actual page size of the entry matches the actual page size specified in \((RB)_{44:51}\).
- Either of the following is true:
  - The implementation’s TLB entries do not contain LPID values.
  - The implementation’s TLB entries contain LPID values and TLBE\(_{LPID} = \text{LPIDR}_{LPID}\).

**IS field in RB contains 0b10 or 0b11**

\((RB)_{i:51}\) (bits \(i=40:11\) of the SET field in \((RB)\)) specify a set of TLB entries, where \( i \) is an implementation-dependent value in the range 40:51. Each entry in the set is invalidated if any of the following conditions are met for the entry.
- The implementation’s TLB entries do not contain an LPID value.
- The IS field in RB contains 0b10 or MSR\(_{HV}=0\), the implementation’s TLB entries contain an LPID value, and TLBE\(_{LPID} = \text{LPIDR}_{LPID}\).
- The IS field in RB contains 0b11 and MSR\(_{HV}=1\).

How the TLB is divided into the \(52^i\) sets is implementation-dependent. The relationship of virtual addresses to these sets is also implementation-dependent. However, if, in an implementation, there can be multiple TLB entries for the same virtual address and same partition, then all these entries must be in a single set.

If the IS field in RB contains 0b10 or 0b11, it is implementation-dependent whether implementation-specific lookaside information that contains translations of effective addresses to real addresses is invalidated.

\(RB_{0:39}\) (when \((RB)_{52:53} = 0b10\) or 0b11), \(RB_{59:62}\) (when \((RB)_{52:53} = 0b00\) and \((RB)_{63}=0\)), and \(RB_{54:63}\) (when \((RB)_{52:53} = 0b10\) or 0b11) must contain 0s and are ignored by the hardware. When \(i>40\) and \((RB)_{52:53} = 0b10\) or 0b11, \(RB_{40:i-1}\) may contain any value and are ignored by the hardware.

Only TLB entries on the thread executing the \texttt{tlbiel} instruction are affected.

MSR\(_{SF}\) must be 1 when this instruction is executed; otherwise the results are boundedly undefined.

If the value specified in \((RB)_{54:55}\), \((RB)_{56:58}\) (when \((RB)_{52:53} = 0b00\) and \((RB)_{63} = 0\)), or \((RB)_{44:51}\) (when \((RB)_{52:53} = 0b00\) and \((RB)_{63} = 1\)) is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

This instruction is privileged.

See Section 5.10, “Page Table Update Synchronization Requirements” on page 935 for a description of other requirements associated with the use of this instruction.

**Special Registers Altered:**

None
Chapter 5. Storage Control

**Programming Note**

The primary use of this instruction by hypervisor software is to invalidate TLB entries prior to reassigning a thread to a new logical partition.

For IS = 0b10 or 0b11, it is implementation-dependent whether ERAT entries are invalidated. If the `tlbiel` instruction is being executed due to a partition swap, an `slbia` instruction can be used to invalidate the pertinent ERAT entries. If the `tlbiel` instruction is being executed to invalidate TLB entries with parity or ECC errors, the fact that the corresponding ERAT entries are not invalidated is immaterial. If the `tlbiel` instruction is being executed to invalidate multiple matching TLB entries, the fact that the corresponding ERAT entries are not invalidated is immaterial for implementations that never create multiple matching ERAT entries.

The primary use of this instruction by operating system software is to invalidate TLB entries that were created by the hypervisor using an implementation-specific hypervisor-managed TLB facility, if such a facility is provided.

`tlbiel` may be executed on a given thread even if the sequence `tlbie - eieio - tlbsync - ptesync` is concurrently being executed on another thread.

See also the Programming Notes with the description of the `tlbie` instruction.

---

### TLB Invalidate All

<table>
<thead>
<tr>
<th>X-form</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>tlbia</code></td>
</tr>
</tbody>
</table>

![X-form Diagram](image)

**Programming Note**

`tlbia` does not affect TLBs on other threads.
The `tlbsync` instruction provides an ordering function for the effects of all `tlbiel` instructions executed by the thread executing the `tlbsync` instruction, with respect to the memory barrier created by a subsequent `pte-sync` instruction executed by the same thread. Executing a `tlbsync` instruction ensures that all of the following will occur.

- All TLB invalidations caused by `tlbiel` instructions preceding the `tlbsync` instruction will have completed on any other thread before any data accesses caused by instructions following the `pte-sync` instruction are performed with respect to that thread.

- All storage accesses by other threads for which the address was translated using the translations being invalidated, and all Reference and Change bit updates associated with address translations that were performed by other threads using the translations being invalidated, will have been performed with respect to the thread executing the `pte-sync` instruction, to the extent required by the associated Memory Coherence Required attributes, before the `pte-sync` instruction's memory barrier is created.

The operation performed by this instruction is ordered by the `eieio` (or `sync` or `pte-sync`) instruction with respect to preceding `tlbiel` instructions executed by the thread executing the `tlbsync` instruction. The operations caused by `tlbiel` and `tlbsync` are ordered by `eieio` as a fourth set of operations, which is independent of the other three sets that `eieio` orders.

The `tlbsync` instruction may complete before operations caused by `tlbiel` instructions preceding the `tlbsync` instruction have been performed.

This instruction is hypervisor privileged.

See Section 5.10 for a description of other requirements associated with the use of this instruction.

Special Registers Altered:

None

---

**Programming Note**

`tlbsync` should not be used to synchronize the completion of `tlbiel`.
5.10 Page Table Update Synchronization Requirements

This section describes rules that software must follow when updating the Page Table, and includes suggested sequences of operations for some representative cases.

In the sequences of operations shown in the following subsections, the Page Table Entry is assumed to be for a virtual page for which the base page size is equal to the actual page size. If these page sizes are different, multiple tlbie instructions are needed, one for each PTE corresponding to the virtual page.

In the sequences of operations shown in the following subsections, any alteration of a Page Table Entry (PTE) that corresponds to a single line in the sequence is assumed to be done using a Store instruction for which the access is atomic. Appropriate modifications must be made to these sequences if this assumption is not satisfied (e.g., if a store doubleword operation is done using two Store Word instructions).

Stores are not performed out-of-order, as described in Section 5.5, “Performing Operations Out-of-Order” on page 890. Moreover, address translations associated with instructions preceding the corresponding Store instructions are not performed again after the stores have been performed. (These address translations must have been performed before the store was determined to be required by the sequential execution model, because they might have caused an exception.) As a result, an update to a PTE need not be preceded by a context synchronizing operation.

All of the sequences require a context synchronizing operation after the sequence if the new contents of the PTE are to be used for address translations associated with subsequent instructions.

As noted in the description of the Synchronize instruction in Section 4.4.3 of Book II, address translation associated with instructions which occur in program order subsequent to the Synchronize (and this includes the ptesync variant) may be performed prior to the completion of the Synchronize. To ensure that these instructions and data which may have been speculatively fetched are discarded, a context synchronizing operation is required.

Programming Note

In many cases this context synchronization will occur naturally; for example, if the sequence is executed within an interrupt handler the rfid or hrfid instruction that returns from the interrupt handler may provide the required context synchronization.

Page Table Entries must not be changed in a manner that causes an implicit branch.

5.10.1 Page Table Updates

TLBs are non-coherent caches of the HTAB. TLB entries must be invalidated explicitly with one of the TLB Invalidate instructions.

Unsynchronized lookups in the HTAB continue even while it is being modified. Any thread, including a thread on which software is modifying the HTAB, may look in the HTAB at any time in an attempt to translate a virtual address. When modifying a PTE, software must ensure that the PTE’s V bit is 0 if the PTE is inconsistent (e.g., if the RPN field is not correct for the current AWA field).

Updates of Reference and Change bits by the hardware are not synchronized with the accesses that cause the updates. When modifying doubleword 1 of a PTE, software must take care to avoid overwriting a hardware update of these bits and to avoid having the value written by a Store instruction overwritten by a hardware update.

Software must execute tlbie and tlbsync instructions only as part of the following sequence, and must ensure that no other thread will execute a “conflicting instruction” while the instructions in the sequence are executing on the given thread. In addition to achieving the required system synchronization, the sequence will cause transactions that include accesses to the affected page(s) to fail.

- tlbie instruction(s) specifying the same LPID operand value
- eieio
- tlbsync
- ptesync

Let L be the LPID value specified by the above tlbie instruction(s). The “conflicting instructions” in this case are the following.

- a tlbie instruction that specifies an LPID value that matches the value L
- a tlbsync instruction that is part of a tlbie-eieio-tlbsync-ptesync sequence in which the tlbie instruction(s) specify an LPID value that matches the value L
- an mtspr instruction that modifies the LPIDR, if the modification has either of the following properties.
  - The old LPID value (i.e., the contents of the LPIDR just before the mtspr instruction is executed) is the value L
  - The new LPID value (i.e., the value specified by the mtspr instruction) is the value L

Other instructions (excluding mtspr instructions that modify the LPIDR as described above, and excluding...
**tlbie** instructions except as shown) may be interleaved with the instruction sequence shown above, but the instructions in the sequence must appear in the order shown. On systems consisting of only a single-threaded processor, the **eieio** and **tlbsync** instructions can be omitted.

---

**Programming Note**

The **eieio** instruction prevents the reordering of the preceding **tlbie** instructions with respect to the subsequent **tlbsync** instruction. The **tlbsync** instruction and the subsequent **ptesync** instruction together ensure that all storage accesses for which the address was translated using the translations being invalidated (by the **tlbie** instructions), and all Reference and Change bit updates associated with address translations that were performed using the translations being invalidated, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required attributes, before any data accesses caused by instructions following the ptesync instruction are performed with respect to that thread or mechanism.

For Page Table update sequences that mark the PTE invalid (see Section 5.10.1.2, "Modifying a Page Table Entry"), Reference and Change bit updates can continue to be performed in the invalid PTE until the **ptesync** at the end of the **tlbie/eieio/tlbsync/ptesync** sequence has completed. Any access to the PTE, by software, that should be performed after all such implicit PTE updates have completed, such as reading the final values of the Reference and Change bits or modifying PTE bytes that contain those bits, must be placed after this **ptesync**.

Before permitting an **mtspr** instruction that modifies the LPIDR to be executed on a given thread, software must ensure that no other thread will execute a “conflicting instruction” until after the **mtspr** instruction followed by a context synchronizing instruction have been executed on the given thread (a context synchronizing event can be used instead of the context synchronizing instruction; see Chapter 12).

The “conflicting instructions” in this case are the following.

- A **tlbie** instruction specifying an LPID operand value that matches either the old or the new LPIDR\_LPID value
- A **tlbsync** instruction that is part of a **tlbie/eieio/tlbsync/ptesync** sequence in which the **tlbie** instruction(s) specify an LPID value that matches either the old or the new LPIDR\_LPID value

---

**Programming Note**

The restrictions specified above regarding modifying the LPIDR apply even on systems consisting of only a single-threaded processor, and even if the new LPID value is equal to the old LPID value.

The sequences of operations shown in the following subsections assume a multi-threaded environment. In an environment consisting of only a single-threaded processor, the **tlbsync** must be omitted, and the **eieio** that separates the **tlbie** from the **tlbsync** can be omitted. In a multi-threaded environment, when **tlbie** is used instead of **tlbie** in a Page Table update, the synchronization requirements are the same as when **tlbie** is used in an environment consisting of only a single-threaded processor.

---

For all of the sequences shown in the following subsections, if it is necessary to communicate completion of the sequence to software running on another thread, the **ptesync** instruction at the end of the sequence should be followed by a **Store** instruction that stores a chosen value to some chosen storage location X. The memory barrier created by the **ptesync** instruction ensures that if a **Load** instruction executed by another thread returns the chosen value from location X, the sequence’s stores to the Page Table have been performed with respect to that other thread. The **Load** instruction that returns the chosen value should be followed by a context synchronizing instruction in order to ensure that all instructions following the context synchronizing instruction will be fetched and executed using the values stored by the sequence (or values stored subsequently). (These instructions may have been fetched or executed out-of-order using the old contents of the PTE.)

This Note assumes that the Page Table and location X are in storage that is Memory Coherence Required.

---

### 5.10.1.1 Adding a Page Table Entry

This is the simplest Page Table case. The V bit of the old entry is assumed to be 0. The following sequence can be used to create a PTE, maintain a consistent state, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

```
PTEA[RPH,LP,AC,R,C,WIMG,PP] ← new values
eieio    /* order 1st update before 2nd */
PTEA[AVA,SM,L,H,V] ← new values (V=1)
ptesync  /* order updates before next Page Table search and before
```

---

---
5.10.1.2 Modifying a Page Table Entry

General Case

If a valid entry is to be modified and the translation instantiated by the entry being modified is to be invalidated, the following sequence can be used to modify the PTE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes. (The sequence is equivalent to deleting the PTE and then adding a new one; see Sections 5.10.1.1 and 5.10.1.3.)

Modifying the SW field

If the only change being made to a valid entry is to modify the SW field, the following sequence suffices, because the SW field is not used by the hardware and doubleword 0 of the PTE is not modified by the hardware.

```
loop: ldarx r1 ← PTE_dwd_0 /* load dwd 0 of PTE */
      r157:60 ← new SW value /* replace SW in r1 */
      stdcx. PTE_dwd_0 ← r1 /* store dwd 0 of PTE if still reserved (new SW value, other fields unchanged) */
      bne loop /* loop if lost reservation */
```

A ldarx/stbctx., lharc/sthctx., or lwarx/stwctx. pair (specifying the low-order byte, halfword, or word respectively of doubleword 0 of the PTE) can be used instead of the ldarx/stdcx. pair shown above.

Modifying the Virtual Address

If the virtual address translated by a valid PTE is to be modified and the new virtual address hashes to the same PTEG (or the same two PTEGs if the secondary Page Table search is enabled) as does the old virtual address, the following sequence can be used to modify the PTE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

```
PTEAVA,SW,L,H,V ← new values (V=1)
ptesync /* order update before tlbie and before next Page Table search */
tlbie(old_B,old_VA14:77-b,old_L,old_LP,old_AP, old_LPID) /*invalidate old translation*/
eieio /* order tlbie before tlbsync */
tlbsync /* order tlbie before ptesync */
ptesync /* order tlbie, tlbsync and 1st update before 2nd update */
```

5.10.1.3 Deleting a Page Table Entry

The following sequence can be used to ensure that the translation instantiated by an existing entry is no longer available.

```
PTEV ← 0 /* (other fields don’t matter) */
ptesync /* order update before tlbie and before next Page Table search */
tlbie(old_B,old_VA14:77-b,old_L,old_LP,old_AP, old_LPID) /*invalidate old translation*/
eieio /* order tlbie before tlbsync */
tlbsync /* order tlbie before ptesync */
ptesync /* order tlbie, tlbsync, and update before next data access */
```
Chapter 6. Interrupts

6.1 Overview

The Power ISA provides an interrupt mechanism to allow the thread to change state as a result of external signals, errors, or unusual conditions arising in the execution of instructions.

System Reset and Machine Check interrupts are not ordered. All other interrupts are ordered such that only one interrupt is reported, and when it is processed (taken) no program state is lost. Since Save/Restore Registers SRR0 and SRR1 are serially reusable resources used by most interrupts, program state may be lost when an unordered interrupt is taken.

6.2 Interrupt Registers

6.2.1 Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Machine Status Save/Restore registers (SRR0 and SRR1). Section 6.5 describes which registers are altered by each interrupt.

Figure 40. Save/Restore Registers

SRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for SRR1 bits in the range 33:36, 42:43, and 45:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set SRR1 (including implementation-dependent setting, e.g. by implementation-specific interrupts).

The SRR0 and SRR1 are hypervisor resources; see Chapter 2.

6.2.2 Hypervisor Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Hypervisor Machine Status Save/Restore registers (HSRR0 and HSRR1). Section 6.5 describes which registers are altered by each interrupt.

Figure 41. Hypervisor Save/Restore Registers

HSRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for HSRR1 bits in the range 33:36 and 42:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set HSRR1 (including implementation-dependent setting, e.g. by implementation-specific interrupts).

The HSRR0 and HSRR1 are hypervisor resources; see Chapter 2.

6.2.3 Data Address Register

The Data Address Register (DAR) is a 64-bit register that is set by the Machine Check, Data Storage, Data Segment, and Alignment interrupts; see Sections 6.5.2, 6.5.3, 6.5.4, and 6.5.8. In general, when one of these interrupts occurs the DAR is set to an effective address associated with the storage access that caused the
interrupt, with the high-order 32 bits of the DAR set to 0 if the interrupt occurs in 32-bit mode.

Figure 42. Data Address Register

6.2.4 Hypervisor Data Address Register

The Hypervisor Data Address Register (HDAR) is a 64-bit register that is set by the Hypervisor Data Storage Interrupt; see Section 6.5.16. In general, when this interrupt occurs, the HDAR is set to an effective address associated with the storage access that caused the interrupt, with the high-order 32 bits of the HDAR set to 0 if the interrupt occurs in 32-bit mode.

Figure 43. Hypervisor Data Address Register

6.2.5 Data Storage Interrupt Status Register

The Data Storage Interrupt Status Register (DSISR) is a 32-bit register that is set by the Machine Check, Data Storage, Data Segment, and Alignment interrupts; see Sections 6.5.2, 6.5.3, 6.5.4, and 6.5.8. In general, when one of these interrupts occurs the DSISR is set to indicate the cause of the interrupt.

Figure 44. Data Storage Interrupt Status Register

DSISR bits may be treated as reserved in a given implementation if they are specified as being set either to 0 or to an undefined value for all interrupts that set the DSISR (including implementation-dependent setting, e.g. by the Machine Check interrupt or by implementation-specific interrupts).

6.2.6 Hypervisor Data Storage Interrupt Status Register

The Hypervisor Data Storage Interrupt Status Register (HDSISR) is a 32-bit register that is set by the Hypervisor Data Storage interrupt. In general, when one of these interrupts occurs the HDSISR is set to indicate the cause of the interrupt.

Figure 45. Hypervisor Data Storage Interrupt Status Register

6.2.7 Hypervisor Emulation Instruction Register

The Hypervisor Emulation Instruction Register (HEIR) is a 32-bit register that is set by the Hypervisor Emulation Assistance interrupt; see Section 6.5.18. The image of the instruction that caused the interrupt is loaded into the register.

Figure 46. Hypervisor Emulation Instruction Register

6.2.8 Hypervisor Maintenance Exception Register

Each bit in the Hypervisor Maintenance Exception Register (HMER) is associated with one or more causes of the Hypervisor Maintenance exception, and is set when the associated exception(s) occur. If the corresponding bit in the Hypervisor Maintenance Exception Enable Register (HMEER) is set, a Hypervisor Maintenance Interrupt (HMI) may occur. If the thread is in a power-saving mode when the interrupt would have occurred, the thread will exit the power-saving mode; see Section 6.5.19 and Section 3.3.2.

Figure 47. Hypervisor Maintenance Exception Register

The contents of the HMER are as follows:

- 0 Set to 1 for a Malfunction Alert.
- 1 Set to 1 when performance is degraded for thermal reasons.
- 2 Set to 1 when thread recovery is invoked.
- Others Implementation-specific.

When the mtspr instruction is executed with the HMER as the encoded Special Purpose Register, the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an mthmer instruction.
6.2.9 Hypervisor Maintenance Exception Enable Register

The Hypervisor Maintenance Exception Enable Register (HMEER) is a 64-bit register in which each bit enables the corresponding exception in the HMER to cause the Hypervisor Maintenance interrupt, potentially causing exit from power-saving mode; see Section 6.5.19 and Section 3.3.2.

Figure 48. Hypervisor Maintenance Exception Enable Register

6.2.10 Facility Status and Control Register

The Facility Status and Control Register (FSCR) controls the availability of various facilities in problem state and indicates the cause of a Facility Unavailable interrupt.

When the FSCR makes a facility unavailable, attempted usage of the facility in problem state is treated as follows:

- Execution of an instruction causes a Facility Unavailable interrupt.
- Access of an SPR using mfspr/mtspr causes a Facility Unavailable interrupt
- rfebb, rfid, rfsvc, hrfid and mtmsr[d] instructions have the same effect on bits in system registers as they would if the bits were available.

Programming Note

The FSCR does not prevent rfebb instructions from attempting to set bits in System Registers that the FSCR makes unavailable. Thus changes to BES-CR15 made by the operating system have the potential to result in an illegal transaction state transition when rfebb is subsequently executed in problem state, resulting in the occurrence of a TM Bad Thing type Program interrupt.

The MSR can also make the Transactional Memory facility unavailable in any privilege state, and MMC0_PMCC can make various components of the Performance Monitor unavailable when accessed problem state. An access to one of these facilities when it is unavailable causes a Facility Unavailable interrupt.

When the PCR makes a facility unavailable in problem state, the facility is treated as not implemented in problem state; any Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur.

When a Facility Unavailable interrupt occurs, the unavailable facility that was accessed is indicated in the most-significant byte of the FSCR.

Figure 49. Facility Status and Control Register

The contents of the FSCR are specified below.

</table>
The Event-Based Branch facility SPRs and instructions are not available in problem state, and event-based exceptions and branches do not occur.

The Event-Based Branch facility SPRs and instructions are available in problem state unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other registers.

The Event-Based Branch facility SPRs and instructions are available in problem state unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other registers.

HFSCR58:60 are used to control the availability of Transactional Memory, the Performance Monitor, and the BHRB in problem and privileged states. FSCR58:60 are reserved since the availability of Transactional Memory is controlled by the MSR, and the availability of the Performance Monitor and BHRB is controlled by MMCR0.

When an OS has set the FSCR such that a facility is unavailable, the OS should either emulate the facility when it is accessed or provide an application interface that requires the application to request use of the facility before it accesses the facility.

When the PCR makes a facility unavailable in problem state, the facility is treated as not implemented in problem state; any Hypervisor Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur as a result of problem-state access. See Section 2.6 for additional information.)

When a Hypervisor Facility Unavailable interrupt occurs, the facility that was accessed is indicated in the most-significant byte of the HFSCR.

When the PCR makes a facility unavailable in problem state, the facility is treated as not implemented in problem state; any Hypervisor Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur as a result of problem-state access. See Section 2.6 for additional information.)

6.2.11 Hypervisor Facility Status and Control Register

The Hypervisor Facility Status and Control Register (HFSCR) controls the available of various facilities in problem and privileged states, and indicates the cause of a Hypervisor Facility Unavailable interrupt.

When the HFSCR makes a facility unavailable, attempted usage of the facility in problem or privileged states is treated as follows:

- Execution of an instruction causes a Hypervisor Facility Unavailable interrupt.
- Access of an SPR using mfspr/mtspr causes a Hypervisor Facility Unavailable interrupt
- rfebb, rfid, rfscv, [h]rfid and mtmsr[d] instructions have the same effect on bits in system registers as they would if the bits were available.

Because the HFSCR does not prevent mtspr, rfscv, [h]rfid, and mtmsr[d] instructions from setting bits in system registers that the HFSCR will make unavailable after a transition to a lower privilege state, these instructions may cause interrupts in a variety of unexpected ways. For example, consider a hypervisor that sets HSRR1 such that hrfid returns to a lower privilege state with MSR[TS] nonzero. A TM Bad Thing interrupt will result, despite that TM is made unavailable by the HFSCR.

Similarly, the HFSCR does not prevent rfebb instructions from attempting to set bits in System Registers that the HFSCR makes unavailable. Thus changes to BESCR[TS] made by the hypervisor have the potential to result in an illegal transaction state transition when rfebb is subsequently executed in problem or privileged state, resulting in the occurrence of a TM Bad Thing type Program interrupt.

When the PCR makes a facility unavailable in problem state, the facility is treated as not implemented in problem state; any Hypervisor Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur as a result of problem-state access. See Section 2.6 for additional information.)

When a Hypervisor Facility Unavailable interrupt occurs, the facility that was accessed is indicated in the most-significant byte of the HFSCR.
| 0 | Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are not available in problem and privileged states; read and write operations to privileged Performance Monitor registers (SPRs 784-792, 795-798) are not available in privileged state. (See the definition of MMCR0PMCC in Section 9.4.4 for a definition of groups A and B.) |
| 1 | Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are available in problem and privileged states unless made unavailable by another register; read and write operations to privileged Performance Monitor registers (SPRs 784-792, 795-798) are available in privileged state. |
| 8:63 | **Facility Enable (FE)** |
| The FE field controls the availability of various facilities in problem and privileged states as specified below. |
| 8:54 | Reserved |
| 55 | **Target Address Register (TAR)** |
| 0 | The TAR and `bctar` instruction are not available in problem and privileged state. |
| 1 | The TAR and `bctar` instruction are available in problem and privileged state unless made unavailable by another register. |
| 56 | **Event-Based Branch Facility (EBB)** |
| 0 | The Event-Based Branch facility SPRs and instructions are not available in problem and privileged states, and event-based exceptions and branches do not occur. |
| 1 | The Event-Based Branch facility SPRs and instructions are available in problem and privileged states unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other bits. |
| 58 | **Transactional Memory Facility (TM)** |
| 0 | The Transactional Memory Facility SPRs and instructions are not available in problem and privileged states. |
| 1 | The Transactional Memory Facility SPRs and instructions are available in problem and privileged states unless made unavailable by another register. |
| 59 | **BHRB Instructions (BHRB)** |
| 0 | The BHRB instructions (`mfbhrb`, `clrbhrb`) are not available in problem and privileged states. |
| 1 | The BHRB instructions (`mfbhrb`, `clrbhrb`) are available in problem and privileged states unless made unavailable by another register. |
| 60 | **Performance Monitor Facility SPRs (PM)** |
| 0 | Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are not available in problem and privileged states; read and write operations to privileged Performance Monitor registers (SPRs 784-792, 795-798) are not available in privileged state. (See the definition of MMCR0PMCC in Section 9.4.4 for a definition of groups A and B.) |
| 1 | Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are available in problem and privileged states unless made unavailable by another register; read and write operations to privileged Performance Monitor registers (SPRs 784-792, 795-798) are available in privileged state. |
| 61 | **Data Stream Control Register (DSCR)** |
| 0 | SPR 3 is not available in problem or privileged states and SPR 17 is not available in privileged state. |
| 1 | SPR 3 is available in problem and privileged states and SPR 17 is available in privileged state unless made unavailable by another register. |
| 62 | **Vector and VSX Facilities (VECVSX)** |
| 0 | The facilities whose availability is controlled by either MSR_VEC or MSR_VSX are not available in problem and privileged states. |
| 1 | The facilities whose availability is controlled by either MSR_VEC or MSR_VSX are available in problem and privileged states unless made unavailable by another register. |
| 63 | **Floating Point Facility (FP)** |
| 0 | The facilities whose availability is controlled by MSR_FP are not available in problem and privileged states. |
| 1 | The facilities whose availability is controlled by MSR_FP are available in problem and privileged states unless made unavailable by another register. |
The FSCR can be used to determine whether a particular facility is being used by an application, and the HFSCR can be used to determine whether a particular facility is being used by either an application or by an operating system. This is done by disabling the facility initially, and enabling it in the interrupt handler upon first usage. The information about the usage of a particular facility can be used to determine whether that facility's state must be saved and restored when changing program context.
### Programming Note

The following tables summarize the interrupts that occur as a result of accessing the non-privileged Performance Monitor registers in problem state when MMCR0_PMC0, PCR, and HFSCR are set to various values. (Accesses to privileged Performance Monitor SPRs (SPRs 784-792, 795-798) in problem state result in Privileged Instruction Type Program interrupts.)

#### Notes:

4. Terminology:
   - FU: Facility Unavailable interrupt
   - HE: Hypervisor Emulation Assistance interrupt
   - HU: Hypervisor Facility Unavailable interrupt

5. Write operations to this SPR are not implemented for all privilege states. (See the `mfspr` instruction description in Section 4.4.4 for additional information.) FU or HU interrupts do not occur regardless of the value of MMCR0_PMC0 or HFSCR.

6. When the PCR indicates a version of the architecture prior to V 2.07, this SPR is treated as not implemented in problem state; no FU or HU interrupts occur regardless of the value of MMCR0_PMC0 or HFSCR.

7. An HU interrupt occurs if HFSCR=0 when this register is accessed in either problem state or privileged (but not hypervisor) state.
6.3 Interrupt Synchronization

When an interrupt occurs, SRR0 or HSRR0 is set to point to an instruction such that all preceding instructions have completed execution, no subsequent instruction has begun execution, and the instruction addressed by SRR0 or HSRR0 may or may not have completed execution, depending on the interrupt type.

With the exception of System Reset and Machine Check interrupts, all interrupts are context synchronizing as defined in Section 1.5.1. System Reset and Machine Check interrupts are context synchronizing if they are recoverable (i.e., if bit 62 of SRR1 is set to 1 by the interrupt). If a System Reset or Machine Check interrupt is not recoverable (i.e., if bit 62 of SRR1 is set to 0 by the interrupt), it acts like a context synchronizing operation with respect to subsequent instructions. That is, a non-recoverable System Reset or Machine Check interrupt need not satisfy items 1 through 3 of Section 1.5.1, but does satisfy items 4 and 5.

6.4 Interrupt Classes

Interrupts are classified by whether they are directly caused by the execution of an instruction or are caused by some other system exception. Those that are “system-caused” are:

- System Reset
- Machine Check
- External
- Decrementer
- Directed Privileged Doorbell
- Hypervisor Decrementer
- Hypervisor Maintenance
- Directed Hypervisor Doorbell
- Performance Monitor

External, Decrementer, Hypervisor Decrementer, Directed Privileged Doorbell, Directed Hypervisor Doorbell, and Hypervisor Maintenance interrupts are maskable interrupts. Therefore, software may delay the generation of these interrupts. System Reset and Machine Check interrupts are not maskable.

“Instruction-caused” interrupts are further divided into two classes, precise and imprecise.

6.4.1 Precise Interrupt

Except for the Imprecise Mode Floating-Point Enabled Exception type Program interrupt, all instruction-caused interrupts are precise.

When the fetching or execution of an instruction causes a precise interrupt, the following conditions exist at the interrupt point.

1. SRR0 addresses either the instruction causing the exception or the immediately following instruction.

Which instruction is addressed can be determined from the interrupt type and status bits.

2. An interrupt is generated such that all instructions preceding the instruction causing the exception appear to have completed with respect to the executing thread.

3. The instruction causing the exception may appear not to have begun execution (except for causing the exception), may have been partially executed, or may have completed, depending on the interrupt type.

4. Architecturally, no subsequent instruction has begun execution.

6.4.2 Imprecise Interrupt

This architecture defines one imprecise interrupt, the Imprecise Mode Floating-Point Enabled Exception type Program interrupt.

When an Imprecise Mode Floating-Point Enabled Exception type Program interrupt occurs, the following conditions exist at the interrupt point.

1. SRR0 addresses either the instruction causing the exception or some instruction following that instruction; see Section 6.5.9, “Program Interrupt” on page 959.

2. An interrupt is generated such that all instructions preceding the instruction addressed by SRR0 appear to have completed with respect to the executing thread.

3. The instruction addressed by SRR0 may appear not to have begun execution (except, in some cases, for causing the interrupt to occur), may have been partially executed, or may have completed; see Section 6.5.9.

4. No instruction following the instruction addressed by SRR0 appears to have begun execution.

All Floating-Point Enabled Exception type Program interrupts are maskable using the MSR bits FE0 and FE1. Although these interrupts are maskable, they differ significantly from the other maskable interrupts in that the masking of these interrupts is usually controlled by the application program, whereas the masking of all other maskable interrupts is controlled by either the operating system or the hypervisor.
6.4.3 Interrupt Processing

Associated with each kind of interrupt is an interrupt vector, which contains the initial sequence of instructions that is executed when the corresponding interrupt occurs.

Interrupt processing consists of saving a small part of the thread’s state in certain registers, identifying the cause of the interrupt in other registers, and continuing execution at the corresponding interrupt vector location. When an exception exists that will cause an interrupt to be generated and it has been determined that the interrupt will occur, the following actions are performed. The handling of Machine Check interrupts (see Section 6.5.2) differs from the description given below in several respects.

1. SRR0 or HSRR0 is loaded with an instruction address that depends on the type of interrupt; see the specific interrupt description for details.

2. Bits 33:36 and 42:47 of SRR1 or HSRR1 are loaded with information specific to the interrupt type.

3. Bits 0:32, 37:41, and 48:63 of SRR1 or HSRR1 are loaded with a copy of the corresponding bits of the MSR.

4. The MSR is set as shown in Figure 51 on page 951. In particular, MSR bits IR and DR are set as specified by LPCRAIL (see Section 2.2), and MSR bit SF is set to 1, selecting 64-bit mode. The new values take effect beginning with the first instruction executed following the interrupt.

5. Instruction fetch and execution resumes, using the new MSR value, at the effective address specific to the interrupt type. These effective addresses are shown in Figure 52 on page 952. An offset may be applied to get the effective addresses, as specified by LPCRAIL (see Section 2.2).

Interrupts do not clear reservations obtained with lbarx, lharx, lwarx, ldarx, or lqarx.

Programming Note

In general, when an interrupt occurs, the following instructions should be executed by the operating system before dispatching a “new” program.

- **stbcx, sthcx, stwcx, stdcx, or stqcx**, to clear the reservation if one is outstanding, to ensure that a lbarx, lharx, lwarx, ldarx, or lqarx in the interrupted program is not paired with a stbcx, sthcx, stwcx, stdcx, or stqcx on the “new” program.

- **sync**, to ensure that all storage accesses caused by the interrupted program will be performed with respect to another thread before the program is resumed on that other thread.

- **isync or rfid**, to ensure that the instructions in the “new” program execute in the “new” context.

- **treclaim**, to ensure that any previous use of the transactional facility is terminated.
For instruction-caused interrupts, in some cases it may be desirable for the operating system to emulate the instruction that caused the interrupt, while in other cases it may be desirable for the operating system not to emulate the instruction. The following list, while not complete, illustrates criteria by which decisions regarding emulation should be made. The list applies to general execution environments; it does not necessarily apply to special environments such as program debugging, bring-up, etc.

In general, the instruction should be emulated if:

- The interrupt is caused by a condition for which the instruction description (including related material such as the introduction to the section describing the instruction) implies that the instruction works correctly. Example: Alignment interrupt caused by `lmw` for which the storage operand is not aligned, or by `dcbz` for which the storage operand is in storage that is Write Through Required or Caching Inhibited.

- The instruction is an illegal instruction that should appear, to the program executing it, as if it were supported by the implementation. Example: A Hypervisor Emulation Assistance interrupt is caused by `imw` for which the instruction description states, potentially to cause the interrupt. Example: Alignment interrupt caused by `lwax` for which the storage operand is not aligned.

- The program is attempting to perform a function that it should not be permitted to perform. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should not be permitted to access. (If the function is one that the program should be permitted to perform, the conditions that caused the interrupt should be corrected and the program re-dispatched such that the instruction will be re-executed. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should be permitted to access but for which there currently is no PTE that satisfies the Page Table search.)

In general, the instruction should not be emulated if:

- The purpose of the instruction is to cause an interrupt. Example: System Call interrupt caused by `sc`.

- The interrupt is caused by a condition that is stated, in the instruction description, potentially to cause the interrupt. Example: Alignment interrupt caused by `lwax` for which the storage operand is not aligned.

- The program is attempting to perform a function that it should not be permitted to perform. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should not be permitted to access. (If the function is one that the program should be permitted to perform, the conditions that caused the interrupt should be corrected and the program re-dispatched such that the instruction will be re-executed. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should be permitted to access but for which there currently is no PTE that satisfies the Page Table search.)
6.4.4 Implicit alteration of HSRR0 and HSRR1

Executing some of the more complex instructions may have the side effect of altering the contents of HSRR0 and HSRR1. The instructions listed below are guaranteed not to have this side effect. Any omission of instruction suffixes is significant; e.g., add is listed but add. is excluded.

1. Branch instructions
   - bl[a], bc[l][a], bcr[l], bctcr[l]
2. Fixed-Point Load and Store Instructions
   - lbz, lbzx, lh, lhz, lw, lwz, ld<64>, ld<64>,
   - stb, stbx, sth, sthx, stw, stwx, std<64>,
   - stdx<64>

Execution of these instructions is guaranteed not to have the side effect of altering HSRR0 and HSRR1 only if the storage operand is aligned and MSRDR=0.

3. Arithmetic instructions
   - addi, adds, add, subf, neg

4. Compare instructions
   - cmpi, cmp, cmpli, cmpl

5. Logical and Extend Sign instructions
   - ori, oris, xor, xoris, and, or, xor, and, or, eqv, andc, orc, extsb, extsh, extsw

6. Rotate and Shift instructions
   - rldicl<64>, rldicr<64>, rldic<64>, rlwinm,
   - rldcl<64>, rldcr<64>, rlwinm, rldimi<64>, rlwimi,

7. Other instructions
   - isync
   - rfid, hrfid
   - mtspr, mfspr, mtmsrd, mfmsr

These instructions, and the other excluded instructions, may be implemented with the assistance of the Hypervisor Emulation Assistance interrupt, or of implementation-specific interrupts that modify HSRR0 and HSRR1. The included instructions are guaranteed not to be implemented thus. (The included instructions are sufficiently simple as to be unlikely to need such assistance. Moreover, they are likely to be needed in interrupt handlers before HSRR0 and HSRR1 have been saved or after HSRR0 and HSRR1 have been restored.)

Similarly, fetching instructions may have the side effect of altering the contents of HSRR0 and HSRR1 unless MSRIR=0.

Programming Note

In order to handle Machine Check and System Reset interrupts correctly, the operating system should manage MSRRI as follows.

- In the Machine Check and System Reset interrupt handlers, interpret SRR1 bit 62 (where MSRRI is placed) as:
  - 0: interrupt is not recoverable
  - 1: interrupt is recoverable

- In each interrupt handler, when enough state has been saved that a Machine Check or System Reset interrupt can be recovered from, set MSRRI to 1.

- In each interrupt handler, do the following (in order) just before returning.
  1. Set MSRRI to 0.
  2. Set SRR0 and SRR1 to the values to be used by rfid. The new value of SRR1 should have bit 62 set to 1 (which will happen naturally if SRR1 is restored to the value saved there by the interrupt, because the interrupt handler will not be executing this sequence unless the interrupt is recoverable).
  3. Execute rfid.

For interrupts that set the SRRs other than Machine Check or System Reset, MSRRI can be managed similarly when these interrupts occur within interrupt handlers for other interrupts that set the SRRs.

This Note does not apply to interrupts that set the HSRRs because these interrupts put the thread into hypervisor state, and either do not occur or can be prevented from occurring within interrupt handlers for other interrupts that set the HSRRs.
6.5 Interrupt Definitions

Figure 51 shows all the types of interrupts and the values assigned to the MSR for each. Figure 52 shows the effective address of the interrupt vector for each interrupt type. (Section 5.7.4 on page 895 summarizes all architecturally defined uses of effective addresses, including those implied by Figure 52.)

Settings for Other Bits:

Bits BE, FP, PR, SE, TM\(^5\), SLE, VEC\(^1\), VSX\(^2\), and PMM are set to 0.

If the interrupt results in HV being equal to 1, the LE bit is copied from the HILE bit; otherwise the LE bit is copied from the LPCRILE bit.

The SF bit is set to 1.

If the TS field contained 0b10 (Transactional) when the interrupt occurred, the TS field is set to 0b01 (Suspended); otherwise the TS field is not altered.

Reserved bits are set as if written as 0.

Figure 51. MSR setting due to interrupt
## 6.5.1 System Reset Interrupt

If a System Reset exception causes an interrupt that is not context synchronizing or causes the loss of a Machine Check exception or a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

When the thread is in any power-saving level, a System Reset interrupt occurs when a System Reset exception exists. When the thread is in doze or nap power-saving levels, a System Reset interrupt occurs when any of the following exceptions exists provided that the exception is enabled to cause exit from power saving mode (see Section 2.2, "Logical Partitioning Control Register (LPCR)"). When the thread is in sleep or rvwinkle power-saving level, it is implementation-specific whether the following exceptions, when enabled, cause exit, or whether only a system-reset causes exit.

- **External**
- **Decrementer**
- **Directed Privileged Doorbell <S.PC>**
- **Directed Hypervisor Doorbell <S.PC>**
- **Hypervisor Maintenance**
- **Implementation-specific**

SRR1 indicates the exception that caused exit from power-saving mode as specified below.

The following registers are set:

- **SRR0**  
  - If the interrupt did not occur when the thread was in power-saving mode, set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present; otherwise, set to an undefined value.

- **SRR1**  
  - **33**  
    - Implementation-dependent.

- **34:36**  
  - Set to 0.

- **42:45**  
  - If the interrupt did not occur when the thread was in power-saving mode, set to an implementation-specific value. If the interrupt occurred when the thread was in power-saving mode, set to indicate the

---

**Programming Note**

When address translation is disabled, use of any of the effective addresses that are shown as reserved in Figure 52 risks incompatibility with future implementations.

If multiple exceptions that cause exit from power-saving mode exist, the exception reported is the exception corresponding to the interrupt that would have occurred if the same exceptions existed and the thread was not in power-saving mode.

46:47 Set to indicate whether the interrupt occurred when the thread was in power-saving mode and, if so, the extent to which resource state was maintained while the thread was in power-saving mode, as follows:

| 00 | The interrupt did not occur when the thread was in power-saving mode. |
| 01 | The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode. |
| 10 | The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution. |

11 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

**Programming Note**

Although the resources that are maintained in power-saving mode (except in doze power-saving level) are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR146:47, to determine what state to restore. (To avoid implementation-dependence in the portion of the hypervisor that enters power-saving mode, the hypervisor must use the specification of the four instructions to determine what state to save.)

| 62 | If the interrupt did not occur while the thread was in power-saving mode, loaded from bit 62 of the MSR if the thread is in a recoverable state; otherwise set to 0. If the interrupt occurred while the thread was in power-saving mode, set to 1 if the thread is in a recoverable state; otherwise set to 0. |
| Others | Loaded from the MSR. |

### MSR

See Figure 51 on page 951.

In addition, if the interrupt occurs when the thread is in power-saving mode and is caused by an exception other than a System Reset exception, all other registers, except HSRR0 and HSRR1, that would be set by the corresponding interrupt if the exception occurred when the thread was not in power-saving mode are set by the System Reset interrupt, and are set to the values to which they would be set if the exception occurred when the thread was not in power-saving mode.

Execution resumes at effective address 0x0000_0000_0000_0100.

The means for software to distinguish between power-on Reset and other types of System Reset are implementation-dependent.

### 6.5.2 Machine Check Interrupt

The causes of Machine Check interrupts are implementation-dependent. For example, a Machine Check
interrupt may be caused by a reference to a storage location that contains an uncorrectable error or does not exist (see Section 5.6), or by an error in the storage subsystem.

When the thread is not in power-saving mode, Machine Check interrupts are enabled when MSR<sub>ME</sub>=1; if MSR<sub>ME</sub>=0 and a Machine Check exception occurs, the thread enters the Checkstop state. When the thread is in doze or nap power-saving levels, Machine Check interrupts are treated as enabled when LPCR<sub>PECE</sub>[2]=1 and cannot occur when LPCR<sub>PECE</sub>[3]=0. When the thread is in sleep or rrwinkle power-saving level, it is implementation-specific whether Machine Check interrupts are treated as enabled under the same conditions as in doze and nap power-saving level or if they cannot occur. If a Machine Check exception occurs while the thread is in power-saving mode and the Machine Check exception is not enabled to cause exit from power-saving mode, the result is implementation specific.

The Checkstop state may also be entered if an access is attempted to a storage location that does not exist (see Section 5.6), or if an implementation-dependant hardware error occurs that prevents continued operation.

### Disabled Machine Check (Checkstop State)

When a thread is in Checkstop state, instruction processing is suspended and generally cannot be restarted without resetting the thread. Some implementations may preserve some or all of the internal state of the thread when entering Checkstop state, so that the state can be analyzed as an aid in problem determination.

### Enabled Machine Check

If a Machine Check exception causes an interrupt that is not context synchronizing or causes the loss of a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

In some systems, the operating system may attempt to identify and log the cause of the Machine Check.

The following registers are set:

#### SRR0

- If the interrupt did not occur while the thread was in power-saving mode, set on a "best effort" basis to the effective address of some instruction that was executing or was about to be executed when the Machine Check exception occurred; otherwise set to an undefined value.

#### SRR1

- 00 The interrupt did not occur when the thread was in power-saving mode.
- 01 The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode.
- 10 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution.
- 11 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

### Programming Note

Since the hypervisor can save the address of the instruction following the Power-Saving Mode instruction if needed, there is no need for the thread to preserve it and store it into SRR0. Therefore, for ease of implementation, the contents of SRR0 upon exit from power-saving mode are specified to be undefined.
A Machine Check interrupt caused by the existence of multiple SLB entries or TLB entries (or similar entries in implementation-specific translation caches) which translate a given effective or virtual address (see Sections 5.7.6.2 and 5.7.7.3.) must occur while still in the power-saving mode, set to 1 if the thread is in a recoverable state; otherwise set to 0.

The access violates Basic Storage Protection.

The access violates Virtual Page Class Key Storage Protection and LPCRKBV=0.

A Data Address Watchpoint match occurs.

Execution of an ecowx or eciwx instruction is disallowed because EARn=0.

An attempt is made to execute a Fixed-Point Load or Store Caching Inhibited instruction with MSRDR=1 or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.

If a stbcx, sthcx, stwcx, stdcx, or stdcx, instruction would not perform its store in the absence of a Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional Store to the specified effective address would cause a Data Storage interrupt, it is implementation-dependent whether a Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed instruction, a Data Storage interrupt does not occur.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: Set to 0.
- **MSR**: Loaded from the MSR.
- **DSISR**: See Figure 51.
- **DAR**: Set to an implementation-dependent value.
- **Others**: Set to 1 if MSRDR=1 and the translation for an attempted access is not found in the Page Table; otherwise set to 0.
- **Others**: Set to 0.

If a **lq**, **stq**, **lbarx**, **lbarwx**, **ldarx**, **ldarwx**, **lqarx**, **stbcx**, **stbcwx**, **stwcx**, **stwcwx**, **stdcx**, or **stqcx** instruction refers to storage that is Write Through Required or Caching Inhibited.

### Programming Note

Although the resources that are maintained in power-saving mode (except in the doze power-saving level) are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR146:47, to determine what state to restore. (To avoid implementation-dependence in the portion of the hypervisor that enters power-saving mode, the hypervisor must use the specification of the four instructions to determine what state to save.)

### Programming Note

If a Machine Check interrupt is caused by an error in the storage subsystem, the storage subsystem may return incorrect data, which may be placed into registers. This corruption of register contents may occur even if the interrupt is recoverable.
tion that addresses storage that is Write Through Required or Caching Inhibited; otherwise set to 0.

38: Set to 1 for a Store, dcbz, or ecowx instruction; otherwise set to 0.

39: Set to 0.

40: Set to 1 for a Store, dcbz, or ecowx instruction; otherwise set to 0.

41: Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.

42: Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.

43: Set to 1 if execution of an ecixw or ecowx instruction is attempted when EAR_E=0; otherwise set to 0.

44:61: Set to 0.

62: Set to 1 if an attempt is made to execute a Fixed-Point Load or Store Caching Inhibited instruction with MSR_DR=1 or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.

63: Set to 0.

DAR

Set to the effective address of a storage element as described in the following list. The list should be read from the top down; the DAR is set as described by the first item that corresponds to an exception that is reported in the DSISR. For example, if a Load Word instruction causes a storage protection violation and a Data Address Watchpoint match (and both are reported in the DSISR), the DAR is set to the effective address of a byte in the first aligned double-word for which access was attempted in the page that caused the exception.

- a Data Storage exception occurs for reasons other than a Data Address Watchpoint match or, for ecixw and ecowx, EAR_E=0
  - a byte in the block that caused the exception, for a Cache Management instruction
  - a byte in the first aligned quadword for which access was attempted in the page that caused the exception, for a quadword Load or Store instruction (i.e., a Load or Store instruction for which the storage operand is a quadword; “first” refers to address order; see Section 6.7)
  - a byte in the first aligned double-word for which access was attempted in the page that caused the exception, for a non-quadword Load or Store instruction or an ecixw or ecowx instruction

- undefined, for a Data Address Watchpoint match, or if ecixw or ecowx is executed when EAR_E=0

For the cases in which the DAR is specified above to be set to a defined value, if the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

If multiple Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the DSISR. However, if one or more DSI-causing exceptions occur together with a Virtualized Page Class Key Storage Protection exception that occurs when LPCR_KBV=1 and Virtualized Partition Memory is disabled by VPM1=0, an HDSI results, and all of the exceptions are reported in the HDSISR.

Execution resumes at effective address 0x0000_0000_0000_0000, possibly offset as specified in Figure 52.

6.5.4 Data Segment Interrupt

A Data Segment interrupt occurs when no higher priority exception exists and a data access cannot be performed because data address translation is enabled and the effective address of any byte of the storage location specified by a Load, Store, icbi, dcbz, dcbst, dcbf[l], ecixw, or ecowx instruction cannot be translated to a virtual address.

If a stbcx., sthcx., stwcx., stdcx., or stqcx. would not perform its store in the absence of a Data Segment interrupt and a non-conditional Store to the specified effective address would cause a Data Segment interrupt, it is implementation-dependent whether a Data Segment interrupt occurs.

If the XER specifies a length of zero for an indexed Move Assist instruction, a Data Segment interrupt does not occur.

The following registers are set:

SRR0 Set to the effective address of the instruction that caused the interrupt.

SRR1 33:36 Set to 0.

42:47 Set to 0.

Others Loaded from the MSR.

MSR See Figure 51.

DSISR Set to an undefined value.

DAR Set to the effective address of a storage element as described in the following list.

- a byte in the block that caused the exception, for a Cache Management instruction
- a byte in the first aligned quadword for which access was attempted in the
segment that caused the exception, for
a quadword Load or Store instruction
(i.e., a Load or Store instruction for
which the storage operand is a quad-
word; “first” refers to address order:
see Section 6.7)
- a byte in the first aligned doubleword
for which access was attempted in the
segment that caused the exception, for
a non-quadword Load or Store instruc-
tion or an ecxwx or ecowx instruction

If the interrupt occurs in 32-bit mode the
high-order 32 bits of the DAR are set to 0.

Execution resumes at effective address
0x0000_0000_0000_0380, possibly offset as specified
in Figure 52.

--- Programming Note ---
A Data Segment interrupt occurs if MSR_DR=1 and
the translation of the effective address of any byte
of the specified storage location is not found in the
SLB (or in any implementation-specific address
translation lookaside information).

6.5.5 Instruction Storage Interrupt

An Instruction Storage interrupt occurs when no higher
priority exception exists, the value of the expression
\[(MSR_{HV PR} = 0b10) \mid (\neg VPM_0 \& \neg MSR_{IR})
\mid (\neg VPM_1 \& MSR_{IR})\]
is 1, and the next instruction to be executed cannot be
fetched for any of the following reasons.

- Instruction address translation is enabled and the
  virtual address cannot be translated to a real
  address.
- The fetch access violates storage protection.

The following registers are set:

**SRR0**
- Set to the effective address of the instruction
  that the thread would have attempted to exe-
  cute next if no interrupt conditions were
  present (if the interrupt occurs on attempting
  to fetch a branch target, SRR0 is set to the
  branch target address).

**SRR1**
- 33: Set to 1 if MSR_{IR}=1 and the translation for
  an attempted access is not found in the
  Page Table; otherwise set to 0.
- 34: Set to 0.
- 35: Set to 1 if the access is to No-execute or
  Guarded storage; otherwise set to 0.
- 36: Set to 1 if the access is not permitted by
  Figure 32 or 33, as appropriate; otherwise
  set to 0.
- 42: Set to 1 if the access is not permitted by vir-
  tual page class key protection; otherwise
  set to 0.
- 43: Set to 0.

**MSR**
- Loaded from the MSR.

Execution resumes at effective address
0x0000_0000_0000_0400, possibly offset as specified
in Figure 52.

--- Programming Note ---
An Instruction Segment interrupt occurs if
MSR_{IR}=1 and the translation of the effective
address of the next instruction to be executed is not
found in the SLB (or in any implementation-specific
address translation lookaside information).

6.5.6 Instruction Segment
Interrupt

An Instruction Segment interrupt occurs when no
higher priority exception exists and the next instruction
to be executed cannot be fetched because instruction
address translation is enabled and the effective
address cannot be translated to a virtual address.

The following registers are set:

**SRR0**
- Set to the effective address of the instruction
  that the thread would have attempted to exe-
  cute next if no interrupt conditions were
  present (if the interrupt occurs on attempting
  to fetch a branch target, SRR0 is set to the
  branch target address).

**SRR1**
- 33: Set to 0.
- 42: Set to 0.

**Others**
- Loaded from the MSR.

**MSR**
- See Figure 51 on page 951.

Execution resumes at effective address
0x0000_0000_0000_0480, possibly offset as specified
in Figure 52.

--- Programming Note ---
An Instruction Segment interrupt occurs if
MSR_{IR}=1 and the translation of the effective
address of the next instruction to be executed is not
found in the SLB (or in any implementation-specific
address translation lookaside information).

6.5.7 External Interrupt

An External interrupt is classified as being either a
Direct External interrupt or a Mediated External inter-
rupt. Throughout this Book, usage of the phrase “Exter-
nal interrupt”, without further classification, refers to
both a Direct External interrupt and a Mediated External interrupt.

### 6.5.7.1 Direct External Interrupt

A Direct External interrupt occurs when no higher priority exception exists, a Direct External exception exists, and the value of the expression

$$\text{MSREE} \land (\neg\text{LPES}_0 \land (\neg\text{MSRH}_V \land \text{MSRP}))$$

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

When LPES$0$=0, the following registers are set:

- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **Others**: Loaded from the MSR.

When LPES$0$=1, the following registers are set:

- **SRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **Others**: Loaded from the MSR.

Execution resumes at effective address 0x0000_0000_0000_0500, possibly offset as specified in Figure 52.

### Programming Note

Because the value of MSREE is always 1 when the thread is in problem state, the simpler expression

$$\text{MSREE} \land (\neg\text{LPES}_0 \lor \neg\text{MSRH}_V)$$

is equivalent to the expression given above.

### Programming Note

The Direct External exception has the same meaning as the External exception in versions of the architecture prior to Version 2.05.

### 6.5.7.2 Mediated External Interrupt

A Mediated External interrupt occurs when no higher priority exception exists, a Mediated External exception exists (see the definition of LPCRMER in Section 2.2), and the value of the expression

$$\text{MSREE} \land (\neg\text{MSRH}_V \lor \text{MSRP})$$

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

When LPES$0$=0, the following registers are set:

- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **Others**: Loaded from the MSR.

When LPES$0$=1, the following registers are set:

- **SRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **Others**: Loaded from the MSR.

Execution resumes at effective address 0x0000_0000_0000_0500, possibly offset as specified in Figure 52.

### 6.5.8 Alignment Interrupt

An Alignment interrupt occurs when no higher priority exception exists and a data access cannot be performed for any of the following reasons.

- The operand of a Floating-Point Load, a Floating-Point Store, a Vector-Scalar Extension Load, or a Vector-Scalar Extension Store is not word-aligned, or crosses a virtual page boundary.
- The operand of lq, stq, lmw, stmw, lharx, lwarx, ldarx, stcx, stwcx, stdcx, eciwx, ecowx, itdp, ifdp, stfdp, or stfdpx is not aligned.
- The operand of a Load or Store is not aligned and the thread is in Little-Endian mode.
- The instruction is lmw, stmw, lswi, lswx, stswi, or stswx, and the operand is in storage that is Write Through Required or Caching Inhibited, or the thread is in Little-Endian mode.
- The operand of a Load or Store crosses a segment boundary, or crosses a boundary between virtual pages that have different storage control attributes.
- The operand of a Load or Store is not aligned and is in storage that is Write Through Required or Caching Inhibited.
The operand of \texttt{lfdp}, \texttt{lfdp}, \texttt{stfdp}, \texttt{stfdpx}, or \texttt{dcbz} is in storage that is Write Through Required or Caching Inhibited.

If the XER specifies a length of zero for an indexed Move Assist instruction, an Alignment interrupt does not occur.

Setting the DSISR and DAR as described below is optional for implementations on which Alignment interrupts occur rarely, if ever, for cases that the Alignment interrupt handler emulates. For such implementations, if the DSISR and DAR are not set as described below they are set to undefined values.

The following registers are set:

\textbf{SRR0} Set to the effective address of the instruction that caused the interrupt.

\textbf{SRR1}
- \texttt{33:36} Set to 0.
- \texttt{42:47} Set to 0.
- Others Loaded from the MSR.

\textbf{MSR} See Figure 51.

\textbf{DSISR}
- \texttt{32:43} Set to 0.
- \texttt{44:45} Set to bits 30:31 of the instruction if DS-form. Set to 0b00 if D-, or X-form.
- \texttt{46} Set to 0.
- \texttt{47:48} Set to bits 29:30 of the instruction if X-form. Set to 0b00 if D- or DS-form.
- \texttt{49} Set to bit 25 of the instruction if D-form. Set to 0b00 if D- or DS-form.
- \texttt{50:53} Set to bits 21:24 of the instruction if X-form. Set to bits 1:4 of the instruction if D- or DS-form.
- \texttt{54:58} Set to bits 6:10 of the instruction (RT/RS/FRT/FRS), except undefined for \texttt{dcbz}.
- \texttt{59:63} Set to bits 11:15 of the instruction (RA) for update form instructions; set to either bits 11:15 of the instruction or to any register number not in the range of registers to be loaded for a valid form \texttt{lmw}, a valid form \texttt{lswi}, or a valid form \texttt{lswx} for which neither RA nor RB is in the range of registers to be loaded; otherwise undefined.

\textbf{DAR} Set to the effective address computed by the instruction, except that if the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

For an X-form \texttt{Load} or \texttt{Store}, it is acceptable for the thread to set the DSISR to the same value that would have resulted if the corresponding D- or DS-form instruction had caused the interrupt. Similarly, for a D- or DS-form \texttt{Load} or \texttt{Store}, it is acceptable for the thread to set the DSISR to the value that would have resulted for the corresponding X-form instruction. For example, an unaligned \texttt{l wax} (that crosses a protection boundary) would normally, following the description above, cause the DSISR to be set to binary:

\begin{verbatim}
0000000000 00 0 01 0 0101 ttttt ??????
\end{verbatim}

where “tttt” denotes the RT field, and “????????” denotes an undefined 5-bit value. However, it is acceptable if it causes the DSISR to be set as for \texttt{lwa}, which is

\begin{verbatim}
0000000000 10 0 00 0 1101 ttttt ??????
\end{verbatim}

If there is no corresponding alternative form instruction (e.g., for \texttt{l wax}), the value described above is set in the DSISR.

The instruction pairs that may use the same DSISR value are:

- \texttt{lhz/lhzx}, \texttt{lhzu/lhzux}, \texttt{lha/lhax}, \texttt{lhma/lhaux}
- \texttt{lwz/lwzx}, \texttt{lwzu/lwzux}, \texttt{lwa/lwax}
- \texttt{id/idx}, \texttt{ldud/ldux}
- \texttt{lsth/sthx}, \texttt{sthu/sthux}
- \texttt{std/stdx}, \texttt{stdu/stdux}
- \texttt{lfs/lfx}, \texttt{lfsu/lfsux}
- \texttt{lfd/lfx}, \texttt{lfdu/lfxu}
- \texttt{sts/strs}, \texttt{stfs/strfs}, \texttt{std/strd}, \texttt{stdf/strfd}

Execution resumes at effective address \texttt{0x0000_0000_0000_0600}, possibly offset as specified in Figure 52.

\textbf{Programming Note}

The architecture does not support the use of an unaligned effective address by \texttt{l harx}, \texttt{l warx}, \texttt{ldarx}, \texttt{sthcx}, \texttt{stwcx}, \texttt{stdcx}, \texttt{eciwx}, and \texttt{ecowx}.

If an Alignment interrupt occurs because one of these instructions specifies an unaligned effective address, the Alignment interrupt handler must not attempt to simulate the instruction, but instead should treat the instruction as a programming error.

\subsection{6.5.9 Program Interrupt}

A Program interrupt occurs when no higher priority exception exists and one of the following exceptions arises during execution of an instruction:

\textbf{Floating-Point Enabled Exception}

A Floating-Point Enabled Exception type Program interrupt is generated when the value of the expression

\begin{verbatim}
(MSRFEO | MSRFE1) & FSPCRFEX
\end{verbatim}

is 1. FSPCRFEX is set to 1 by the execution of a floating-point instruction that causes an enabled exception, including the case of a \texttt{Move To FSPCR}
instruction that causes an exception bit and the corresponding enable bit both to be 1.

**TM Bad Thing Exception [Category: Transactional Memory]**

A TM Bad Thing exception is generated when any of the following occurs.

- An \texttt{rfebb}, \texttt{rifd}, \texttt{hrfid}, or \texttt{mtmsrd} instruction attempts to cause an illegal state transition (see Section 3.2.2).
- An \texttt{rifd}, \texttt{hrfid}, or \texttt{mtmsrd} instruction attempts to cause a transition to Problem state with an active transaction (Transactional or Suspended state) when TM is disabled by the PCR (\texttt{PCR}_{TM}=1 or \texttt{PCR}_{V2,08}=1).
- An \texttt{rfebb} instruction in Problem state attempts to cause a transition to Transactional or Suspended state when \texttt{PCR}_{TM}=1 (i.e. a latent non-zero TS value was in the BESCR).
- An attempt is made to execute \texttt{trechkpt} in Transactional or Suspended state or when \texttt{TEXASR}_{FS}=0.
- An attempt is made to execute \texttt{tend} in Suspended state.
- An attempt is made to execute \texttt{treclaim} in Non-transactional state.
- An attempt is made to execute a \texttt{mtspr} targeting a TM register in other than Non-transactional state.
- An attempt is made to execute a power saving instruction in Suspended state.

**Privileged Instruction**

The following applies if the instruction is executed when MSR\textsubscript{PR} = 1.

A Privileged Instruction type Program interrupt is generated when execution is attempted of a privileged instruction, or of an \texttt{mtspr} or \texttt{mfspr} instruction with an SPR field that contains a value having spr\textsubscript{0}=1.

The following applies if the instruction is executed when MSR\textsubscript{HV\ PR} = 0b00.

A Privileged Instruction type Program interrupt is generated when execution is attempted of an \texttt{mtspr} or \texttt{mfspr} instruction with an SPR field that designates an SPR that is accessible by the instruction only when the thread is in hypervisor state, or when execution of a hypervisor-privileged instruction is attempted.

**Programming Note**

These are the only cases in which a Privileged Instruction type Program interrupt can be generated when MSR\textsubscript{PR}=0. They can be distinguished from other causes of Privileged Instruction type Program interrupts by examining SRR\textsubscript{149} (the bit in which MSR\textsubscript{PR} was saved by the interrupt).

**Trap**

A Trap type Program interrupt is generated when any of the conditions specified in a Trap instruction is met.

The following registers are set:

**SRR0**

For all Program interrupts except a Floating-Point Enabled Exception type Program interrupt, set to the effective address of the instruction that caused the corresponding exception.

For a Floating-Point Enabled Exception Program interrupt, set as described in the following list.

- If MSR\textsubscript{FE0 \ FE1} = 0b00, FPSCR\textsubscript{FE} = 1, and an instruction is executed that changes MSR\textsubscript{FE0 \ FE1} to a nonzero value, set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**Programming Note**

Recall that all instructions that can alter MSR\textsubscript{FE0 \ FE1} are context synchronizing, and therefore are not initiated until all preceding instructions have reported all exceptions they will cause.

- If MSR\textsubscript{FE0 \ FE} = 0b11, set to the effective address of the instruction that caused the Floating-Point Enabled Exception.
- If MSR\textsubscript{FE0 \ FE} = 0b01 or 0b10, set to the effective address of the first instruction that caused a Floating-Point Enabled Exception since the most recent time FPSCR\textsubscript{FE} was changed from 1 to 0 or of some subsequent instruction.

**SRR1**

- Set to 0.
- Set to 1 for a TM Bad Thing Exception type Program interrupt; otherwise set to 0.
- Set to 1 for a Floating-Point Enabled Exception type Program interrupt; otherwise set to 0.
Section 6.5.10  Floating-Point Unavailable Interrupt

A Floating-Point Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a floating-point instruction (including floating-point loads, stores, and moves), and MSR\textsubscript{FP}=0.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**:
  - 33:36: Set to 0.
  - 42:47: Set to 0.
- **Others**: Loaded from the MSR.
- **MSR**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0800, possibly offset as specified in Figure 52.

Section 6.5.11  Decrementer Interrupt

A Decrementer interrupt occurs when no higher priority exception exists, a Decrementer exception exists, and MSR\textsubscript{EE}=1.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **SRR1**:
  - 33:36: Set to 0.
  - 42:47: Set to 0.
- **Others**: Loaded from the MSR.
- **MSR**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0900, possibly offset as specified in Figure 52.

Section 6.5.12  Hypervisor Decrementer Interrupt

A Hypervisor Decrementer interrupt occurs when no higher priority exception exists, a Hypervisor Decrementer exception exists, and the value of the following expression is 1.

\[
\text{MSR}_{\text{EE}} \mid \neg (\text{MSR}_{\text{HV}}) \mid \text{MSR}_{\text{PR}} \mid \text{HDICE}
\]

The following registers are set:

- **HSRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
6.5.13 Directed Privileged Doorbell Interrupt [Category: Server. Processor Control]

A Directed Privileged Doorbell interrupt occurs when no higher priority exception exists, a Directed Privileged Doorbell exception is present, and MSR_EE=1. Directed Privileged Doorbell exceptions are generated when Directed Privileged Doorbell messages (see Chapter 11) are received and accepted by the thread.

Save/Restore Register 0, Save/Restore Register 1 and Machine State Register are updated as follows:

- **Save/Restore Register 0**: Set to the effective address of the next instruction to be executed.
- **Save/Restore Register 1**: Set to the contents of the Machine State Register at the time of the interrupt.
- **Machine State Register**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0980, possibly offset as specified in Figure 52.

---

**Programming Note**

Because the value of MSR_EE is always 1 when the thread is in problem state, the simpler expression

\[(MSR_{EE} \lor \neg(MSR_{HV})) \& HDICE\]

is equivalent to the expression given above.

6.5.14 System Call Interrupt

A System Call interrupt occurs when a System Call instruction is executed.

The following registers are set:

- **SRR0**: Set to the effective address of the instruction following the System Call instruction.
- **SRR1**: Set to 0.
- **Others**: Loaded from the MSR.
- **MSR**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0C00, possibly offset as specified in Figure 52.

---

**Programming Note**

An attempt to execute an `sc` instruction with LEV=1 in problem state should be treated as a programming error.

6.5.15 Trace Interrupt [Category: Trace]

A Trace interrupt occurs when no higher priority exception exists and any instruction except `rfid`, `hrfid`, or a Power-Saving Mode instruction is successfully completed, provided any of the following is true:

- the instruction is `mtmsr[d]` and MSR_S=1 when the instruction was initiated,
- the instruction is not `mtmsr[d]` and MSR_S=1,
- the instruction is a `Branch` instruction and MSR_BE=1, or
- a CIABR match occurs.

Successful completion means that the instruction caused no other interrupt and, if the processor is in the Transactional state <TM>, did not cause the transaction to fail in such a way that the instruction did not complete. (See Section 5.3.1 of Book II). Thus a Trace interrupt never occurs for a System Call instruction, or for a Trap instruction that traps, or for a `dcbf` that is executed in Transactional state. The instruction that causes a Trace interrupt is called the "traced instruction".

When a Trace interrupt occurs, the following registers are set:

- **SRR0**: Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **SRR1**: Set to 1.
- **Others**: Loaded from the MSR.
6.5.16 Hypervisor Data Storage Interrupt

A Hypervisor Data Storage interrupt occurs when no higher priority exception exists, the thread is not in hypervisor state, and either (a) VPM1=0, LPCRKBV=1, and a Virtual Storage Page Class Key Protection exception exists or (b) the value of the expression

\[(VPM_0 \& \neg MSR_{DR}) \mid (VPM_1 \& MSR_{DR})\]

is 1, and a data access cannot be performed for any of the following reasons.

- Data address translation is enabled (MSR_{DR}=1) and the virtual address of any byte of the storage location specified by a Load, Store, icbi, dcbz, dcbst, dcbf[l], eciwx, or ecowx instruction cannot be translated to a real address.
- Data address translation is disabled (MSR_{DR}=0), and the virtual address of any byte of the storage location specified by a Load, Store, icbi, dcbz, dcbst, dcbf[l], eciwx, or ecowx instruction cannot be translated to a real address by means of the virtual real addressing mechanism.
- The effective address specified by a lq, stq, lbarx, lharx, lwarx, ldarx, lqarx, stbcx, sthcx, stwcx, stdcx, or stqcx. instruction refers to storage that is Write Through Required or Caching Inhibited.
- The access violates storage protection.
- A Data Address Watchpoint match occurs.
- Execution of an eciwx or ecowx instruction is disallowed because EARE=0.

If a stbcx, sthcx, stwcx, stdcx, or stqcx. would not perform its store in the absence of a Hypervisor Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional Store to the specified effective address would cause a Hypervisor Data Storage interrupt, it is implementation-dependent whether a Hypervisor Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed Move Assist instruction, a Hypervisor Data Storage interrupt does not occur.

The following registers are set:

| HSRR0 | Set to the effective address of the instruction that caused the interrupt. |
| HSRR1 | 33:36  Set to 0. |
|       | 42:47  Set to 0. |
| Others | Loaded from the MSR. |
| MSR   | See Figure 51. |
| HDSISR | 32  Set to 0. |
|       | 33  Set to 1 if the value of the expression |
|       | (MSR_{DR}) \mid (\neg MSR_{DR} \& VPM_0) |

In general, interrupt handlers can achieve the effect of tracing these instructions.
is 1 and the translation for an attempted access is not found in the Page Table; otherwise set to 0.

34:35
Set to 0.

36
Set to 1 if the access is not permitted by Figure 32 or 33, as appropriate; otherwise set to 0.

37
Set to 1 if the access is due to a \texttt{lsq}, \texttt{stq}, \texttt{ldarx}, \texttt{lwax}, \texttt{ldaxr}, \texttt{lqax}, \texttt{stbcx}, \texttt{sthcx}, \texttt{stwcx}, \texttt{stdcx}, or \texttt{stqcx} instruction that addresses storage that is Write Through Required or Caching Inhibited; otherwise set to 0.

38
Set to 1 if a \texttt{Store}, \texttt{dcbz}, or \texttt{ecowx} instruction; otherwise set to 0.

39:40
Set to 0.

41
Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.

42
Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.

43
Set to 1 if execution of an \texttt{eciwx} or \texttt{ecowx} instruction is attempted when \texttt{EARE}=0; otherwise set to 0.

44:63
Set to 0.

**HDAR**

Set to the effective address of a storage element, as described in the following list. The list should be read from the top down; the HDAR is set as described by the first item that corresponds to an exception that is reported in the HDSISR. For example, if a \texttt{Load Word} instruction causes a storage protection violation and a Data Address Watchpoint match, the HDAR is set to the effective address of a byte in the first aligned doubleword for which access was attempted in the page that caused the exception.

- a Hypervisor Data Storage exception occurs for reasons other than a Data Address Watchpoint match or, for \texttt{eciwx} and \texttt{ecowx}, \texttt{EARE}=0
  - a byte in the block that caused the exception, for a \texttt{Cache Management} instruction
  - a byte in the first aligned quadword for which access was attempted in the page that caused the exception, for a quadword \texttt{Load} or \texttt{Store} instruction (i.e., a \texttt{Load} or \texttt{Store} instruction for which the storage operand is a quadword; “first” refers to address order; see Section 6.7)
  - a byte in the first aligned doubleword for which access was attempted in the page that caused the exception, for a non-quadword \texttt{Load} or \texttt{Store} instruction or an \texttt{eciwx} or \texttt{ecowx} instruction
  - undefined, for a Data Address Watchpoint match, or if \texttt{eciwx} or \texttt{ecowx} is executed when \texttt{EARE}=0

For the cases in which the HDAR is specified above to be set to a defined value, if the interrupt occurs in 32-bit mode the high-order 32 bits of the HDAR are set to 0.

If multiple Hypervisor Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the HDSISR. If the HDSISR reports other exceptions together with a Virtualized Page Class Key Storage Protection exception that occurs when LPCRKBV=1 and Virtualized Partition Memory is disabled by VPM1=0, the other exceptions are actually DSIs.

---

**Programming Note**

A Virtual Page Class Key Storage Protection exception that occurs with LPCRKBV=1 and Virtualized Partition Memory disabled by VPM1=0 identifies an access that must be emulated by the hypervisor. When it is reported together with other exceptions in the HDSISR, the hypervisor should service the Virtual Page Class Key Storage Protection exception first. This is in part because the operating system may be using some PTE fields for non-architected purposes, which could in turn cause spurious exceptions to be reported.

Execution resumes at effective address 0x0000_0000_0000_0E00, possibly offset as specified in Figure 52.

---

**6.5.17 Hypervisor Instruction Storage Interrupt**

A Hypervisor Instruction Storage interrupt occurs when the thread is not in hypervisor state, no higher priority exception exists, the value of the expression $(VPM_0 \& \neg MSR_0) \lor (VPM_1 \& MSR_1)$ is 1, and the next instruction to be executed cannot be fetched for any of the following reasons.

- Instruction address translation is enabled (MSR$_i$=1) and the virtual address cannot be translated to a real address.
- Instruction address translation is disabled (MSR$_i$=0), and the virtual address cannot be translated to a real address by means of the virtual real addressing mechanism.
- The fetch access violates storage protection.

The following registers are set:
**HSR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, HSR0 is set to the branch target address).

**HSRR1**

33 Set to 1 if the value of the expression \((\text{MSR}_{\text{IP}}) \mid (\neg \text{MSR}_{\text{IP}} \& \text{VP}_{\text{PM}})\) is 1 and the translation for an attempted access is not found in the Page Table; otherwise set to 0.

34 Set to 0.

35 Set to 1 if the access is to No-execute or Guarded storage; otherwise set to 0.

36 Set to 1 if the access is not permitted by Figure 32 or 33, as appropriate; otherwise set to 0.

42 Set to 1 if the access is not permitted by virtual page class key protection; otherwise set to 0.

43:47 Set to 0.

Others Loaded from the MSR.

**MSR** See Figure 51.

If multiple Hypervisor Instruction Storage exceptions occur due to attempting to fetch a single instruction, any one or more of the bits corresponding to these exceptions may be set to 1 in HSRR1.

Execution resumes at effective address 0x0000_0000_0000_0E10, possibly offset as specified in Figure 52.

### 6.5.18 Hypervisor Emulation Assistance Interrupt

A Hypervisor Emulation Assistance interrupt is generated when execution is attempted of an illegal instruction, or of a reserved instruction or an instruction that is not provided by the implementation. It is also generated under the following conditions.

- an **mtepr** or **mtepr** instruction is executed when MSR_{PR}=1 if the instruction specifies an SPR with spr_{0}=0 that is not provided by the implementation
- an **mtepr** or **mtepr** instruction is executed when MSR_{PR}=0 if the instruction specifies SPR 0
- an **mtepr** instruction is executed when MSR_{PR}=0 if the instruction specifies SPR 4, 5, or 6

A Hypervisor Emulation Assistance interrupt may be generated when execution is attempted of any of the following kinds of instruction.

- an instruction that is in invalid form
- an **lsdx** instruction for which RA or RB is in the range of registers to be loaded

The following registers are set:

- **HSR0** Set to the effective address of the instruction that caused the interrupt.
- **HSR1**
  - 33:36 Set to 0.
  - 42:47 Set to 0.
  - Others Loaded from the MSR.
- **MSR** See Figure 51 on page 951.
- **HEIR** Set to a copy of the instruction that caused the interrupt

Execution resumes at effective address 0x0000_0000_0000_0E40, possibly offset as specified in Figure 52.

#### Programming Note

If a Hypervisor Emulation Assistance interrupt occurs, when the thread is not in hypervisor state, for an instruction that the hypervisor does not emulate, the hypervisor should pass control to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt", as described in a Programming Note near the end of Section 6.5.9, "Program Interrupt" on page 959.

### 6.5.19 Hypervisor Maintenance Interrupt

A Hypervisor Maintenance interrupt occurs when no higher priority exception exists, a Hypervisor Maintenance exception exists (a bit in the HMER is set to one), the exception is enabled in the HMEER, and the value of the following expression is 1.

\((\text{MSR}_{\text{EE}} \mid \neg (\text{MSR}_{\text{HV}}) \mid \text{MSR}_{\text{PR}})\)

The following registers are set:

- **HSR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
- **HSRR1**
  - 33:36 Set to 0.
  - 42:47 Set to 0.
  - Others Loaded from the MSR.
- **MSR** See Figure 51 on page 951.
- **HMER** See Section 6.2.8 on page 940.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an **mthmtr** instruction.

Execution resumes at effective address 0x0000_0000_0000_0E60.
6.5.20 Directed Hypervisor Doorbell Interrupt [Category: Server.Processor Control]

A Directed Hypervisor Doorbell interrupt occurs when no higher priority exception exists, a Directed Hypervisor Doorbell exception is present, and MSREE=0 | MSRHV=1. Directed Hypervisor Doorbell exceptions are generated when Directed Hypervisor Doorbell messages (see Chapter 11) are received and accepted by the thread.

The following registers are set:
- **SRR0**: Set to the effective address of the instruction that would have been attempted to be executed next if no interrupt conditions were present.
- **SRR1**: 33:36 and 42:47 set to 0. 43:47 set to 0. Others loaded from the MSR.
- **MSR**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0E80, possibly offset as specified in Figure 52.

6.5.22 Vector Unavailable Interrupt [Category: Vector]

A Vector Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a Vector instruction (including Vector loads, stores, and moves), and MSRVEC=0.

The following registers are set:
- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: 33:36 set to 0. 42:47 set to 0. Others loaded from the MSR.
- **MSR**: See Figure 51 on page 951.

Execution resumes at effective address 0x0000_0000_0000_0F20, possibly offset as specified in Figure 52.

6.5.23 VSX Unavailable Interrupt [Category: VSX]

A VSX Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a VSX instruction (including VSX loads, stores, and moves), and MSRVSX=0.

The following registers are set:
- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: 33:36 set to 0. 42:47 set to 0. Others loaded from the MSR.
- **MSR**: See Figure 51 on page 951.
Execution resumes at effective address 0x0000_0000_0000_0F40, possibly offset as specified in Figure 52.

6.5.24 Facility Unavailable Interrupt

A Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.

- a facility is accessed in problem state when it has been made unavailable by the FSCR.
- a Performance Monitor register or instruction (e.g. mtbhrbe, clrbhrb) is accessed in problem state when it has been made unavailable by MMCR0.
- the Transactional Memory Facility is accessed in any privilege state when it has been made unavailable by MSR_TM.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRR0</td>
<td>Set to the effective address of the instruction that caused the interrupt.</td>
</tr>
<tr>
<td>SRR1</td>
<td>Set to 0.</td>
</tr>
<tr>
<td></td>
<td>33:36 Set to 0.</td>
</tr>
<tr>
<td></td>
<td>42:47 Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
<tr>
<td>MSR</td>
<td>See Figure 51 on page 951.</td>
</tr>
<tr>
<td>FSCR</td>
<td>Set to the effective address 0x0000_0000_0000_0F60, possibly offset as specified in Figure 52.</td>
</tr>
<tr>
<td></td>
<td>0:7 See Section 6.2.10 on page 941.</td>
</tr>
<tr>
<td></td>
<td>Others Not changed.</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0F80, possibly offset as specified in Figure 52.

Programming Note

For the case of an outer tbegin, the interrupt handler should either return to the tbegin, with MSR_TM = 1 (allowing the program to use transactions), or treat the attempt to initiate an outer transaction as a program error.

6.5.25 Hypervisor Facility Unavailable Interrupt

A Hypervisor Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.

- a facility is accessed in problem or privileged states when it has been made unavailable by the HFSCR.

The following registers are set:

<table>
<thead>
<tr>
<th>Register</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>HSRR0</td>
<td>Set to the effective address of the instruction that caused the interrupt.</td>
</tr>
<tr>
<td>HSRR1</td>
<td>Set to 0.</td>
</tr>
<tr>
<td>Others</td>
<td>Loaded from the MSR.</td>
</tr>
<tr>
<td>MSR</td>
<td>See Figure 51 on page 951.</td>
</tr>
<tr>
<td>HFSCR</td>
<td>0:7 See Section 6.2.11 on page 942.</td>
</tr>
<tr>
<td>Others</td>
<td>Not changed.</td>
</tr>
</tbody>
</table>

Execution resumes at effective address 0x0000_0000_0000_0F80, possibly offset as specified in Figure 52.
6.6 Partially Executed Instructions

If a Data Storage, Data Segment, Alignment, system-caused, or imprecise exception occurs while a Load or Store instruction is executing, the instruction may be aborted. In such cases the instruction is not completed, but may have been partially executed in the following respects:

- Some of the bytes of the storage operand may have been accessed, except that if access to a given byte of the storage operand would violate storage protection, that byte is neither copied to a register by a Load instruction nor modified by a Store instruction. Also, the rules for storage accesses given in Section 5.8.1, "Guarded Storage" and in Section 2.1 of Book II are obeyed.
- Some registers may have been altered as described in the Book II section cited above.
- Reference and Change bits may have been updated as described in Section 5.7.8.
- For a stbcx, sthcx, stwcx, stdcx, or stdqcx instruction that is executed in-order, CR0 may have been set to an undefined value and the reservation may have been cleared.

The architecture does not support continuation of an aborted instruction but intends that the aborted instruction be re-executed if appropriate.

---

**Programming Note**

An exception may result in the partial execution of a Load or Store instruction. For example, if the Page Table Entry that translates the address of the storage operand is altered, by a program running on another thread, such that the new contents of the Page Table Entry preclude performing the access, the alteration could cause the Load or Store instruction to be aborted after having been partially executed.

As stated in the Book II section cited above, if an instruction is partially executed the contents of registers are preserved to the extent that the instruction can be re-executed correctly. The consequent preservation is described in the following list. For any given instruction, zero, one, or two items in the list apply.

- For a fixed-point Load instruction that is not a multiple or string form, or for an eciwx instruction, if RT=RA or RT=RB then the contents of register RT are not altered.
- For an lq instruction, if RT+1 = RA then the contents of register RT+1 are not altered.
- For an update form Load or Store instruction, the contents of register RA are not altered.
6.7 Exception Ordering

Since multiple exceptions can exist at the same time and the architecture does not provide for reporting more than one interrupt at a time, the generation of more than one interrupt is prohibited. Some exceptions, such as the Mediated External exception, persist and can be deferred. However, other exceptions would be lost if they were not recognized and handled when they occur. For example, if an External interrupt was generated when a Data Storage exception existed, the Data Storage exception would be lost. If the Data Storage exception was caused by a Store Multiple instruction for which the storage operand crosses a virtual page boundary and the exception was a result of attempting to access the second virtual page, the store could have modified locations in the first virtual page even though it appeared that the Store Multiple instruction was never executed.

For the above reasons, all exceptions are prioritized with respect to other exceptions that may exist at the same instant to prevent the loss of any exception that is not persistent. Some exceptions cannot exist at the same instant as some others.

Data Storage, Hypervisor Data Storage, Data Segment, and Alignment exceptions and transaction failure due to attempted access of a disallowed type while in Transactional state occur as if the storage operand were accessed one byte at a time in order of increasing effective address (with the obvious caveat if the operand includes both the maximum effective address and effective address 0). (The required ordering of exceptions on components of non-atomic accesses does not extend to the performing of the component accesses in the event of an exception. For example, if byte n causes a data storage exception, it is not necessarily true that the access to byte n-1 has been performed.)

6.7.1 Unordered Exceptions

The exceptions listed here are unordered, meaning that they may occur at any time regardless of the state of the interrupt processing mechanism. These exceptions are recognized and processed when presented.

1. System Reset
2. Machine Check

6.7.2 Ordered Exceptions

The exceptions listed here are ordered with respect to the state of the interrupt processing mechanism. With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same ordering. The exception is that Virtual Page Class Key Storage Protection exceptions that occur when LPCR KEY=1 and Virtualized Partition Memory is disabled by VPM1=0 cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

System-Caused or Imprecise

1. Program
    1. Imprecise Mode Floating-Point Enabled Exception

4 Trace
4.e Other Instructions
   1 Hypervisor Facility Unavailable
   2 Facility Unavailable
   3a [Hypervisor] Data Storage, [Hypervisor] Data Segment, or Alignment
4 Trace

Exceptions with different numbers have different ordering. Exceptions with the same numbering but different lettering are mutually exclusive and cannot be caused by the same instruction. The External, [Hypervisor] Decrementer, Performance Monitor, Directed Privileged Doorbell <S.PC>, and Directed Hypervisor Doorbell <S.PC> interrupts have equal ordering. Similarly, where Data Storage, Data Segment, and Alignment exceptions are listed in the same item they have equal ordering.

Even on threads that are capable of executing several instructions simultaneously, or out of order, instruction-caused interrupts (precise and imprecise) occur in program order.

6.8 Interrupt Priorities

This section describes the relationship of nonmaskable, maskable, precise, and imprecise interrupts. In the following descriptions, the interrupt mechanism waiting for all possible exceptions to be reported includes only exceptions caused by previously initiated instructions (e.g., it does not include waiting for the Decrementer to step through zero). The exceptions are listed in order of highest to lowest priority. The phrase "corresponding interrupt" means the interrupt having the same name as the exception unless the thread is in power-saving mode, in which case the phrase means the System Reset interrupt.

Unless otherwise stated or obvious from context, it is assumed below that one of the following conditions is satisfied.

- The thread is not in power-saving mode and the interrupt, unless it is the Machine Check interrupt, is not disabled. (For the Machine Check interrupt no assumption is made regarding enablement.)
- The thread is in power-saving mode and the exception is enabled to cause exit from the mode.

With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same priority. The exception is that exceptions caused by Virtual Page Class Key Storage Protection exceptions that occur when LPCR KBV=1 and Virtualized Partition Memory is disabled by VPM=0 cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

1. System Reset

System Reset exception has the highest priority of all exceptions. If this exception exists, the interrupt mechanism ignores all other exceptions and generates a System Reset interrupt.
Once the System Reset interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

2. Machine Check

Machine Check exception is the second highest priority exception. If this exception exists and a System Reset exception does not exist, the interrupt mechanism ignores all other exceptions and generates a Machine Check interrupt.

Once the Machine Check interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

3. Instruction-Caused and Precise

This exception is the third highest priority exception. When this exception is created, the interrupt mechanism waits for all possible Imprecise exceptions to be reported. It then generates the appropriate ordered interrupt if no higher priority exception exists when the interrupt is to be generated. Within this category a particular instruction may present more than a single exception. When this occurs, those exceptions are ordered in priority as indicated in the following lists. Where [Hypervisor] Data Storage, Data Segment, and Alignment exceptions are listed in the same item they have equal priority (i.e., the hardware may generate any one of the three interrupts for which an exception exists). For instructions that are forbidden in Transactional state, transaction failure takes priority over all interrupts except Privileged Instruction type of Program Interrupts. For data accesses that are forbidden in Transactional state, transaction failure has the same priority as the group of “other” [Hypervisor] Data Storage, Data Segment, and Alignment exceptions. (See Section 5.3.1 of Book II).

A. Fixed-Point Loads and Stores
   a. These exceptions are mutually exclusive and have the same priority:
      ■ Hypervisor Emulation Assistance
      ■ Program - Privileged Instruction
   b. Hypervisor Facility Unavailable
   c. Facility Unavailable
   d. Data Storage for the case of Fixed-Point Load or Store Caching Inhibited instructions with MSRDR=1
   e. All other Data Storage, Hypervisor Data Storage, [Hypervisor] Data Segment, or Alignment
   f. Trace

B. Floating-Point Loads and Stores
   a. Hypervisor Emulation Assistance
   b. Hypervisor Facility Unavailable
   c. Floating-Point Unavailable
   d. [Hypervisor] Data Storage, [Hypervisor] Data Segment, or Alignment
   e. Trace

C. Vector Loads and Stores
   a. Hypervisor Emulation Assistance
   b. Hypervisor Facility Unavailable
   c. Vector Unavailable
   d. [Hypervisor] Data Storage, [Hypervisor] Data Segment, or Alignment
   e. Trace

D. VSX Loads and Stores
   a. Hypervisor Emulation Assistance
   b. Hypervisor Facility Unavailable
   c. VSX Unavailable
   d. [Hypervisor] Data Storage, [Hypervisor] Data Segment, or Alignment
   e. Trace

G. Other VSX Instructions
   a. Hypervisor Emulation Assistance
   b. Hypervisor Facility Unavailable
   c. VSX Unavailable
   d. Program - Precise Mode Floating-Point Enabled Exception
   e. Trace

H. TM instruction, mtfspr specifying TM SPR
   a. Program - Privileged Instruction (only for treclaim, trechkpt, and mtsp)
   b. Hypervisor Facility Unavailable
   c. Facility Unavailable
   d. Program - TM Bad Thing (only for treclaim, trechkpt, and mtsp)
   e. Trace

I. rfd, hrfid, rfmb and mtmsr[d]
   a. Program - Privileged Instruction for all except rfebb
   b. Program - TM Bad Thing exception for all except mtsp
   c. Program - Floating-Point Enabled Exception for all except rfebb
   d. Trace, for mtmsr[d] and rfebb only

J. Other Instructions
   a. These exceptions are mutually exclusive and have the same priority:
      ■ Program - Trap
System Call
Program - Privileged Instruction
Hypervisor Emulation Assistance
b. Hypervisor Facility Unavailable
c. Facility Unavailable
d. Trace

K. [Hypervisor] Instruction Storage and Instruction Segment

These exceptions have the lowest priority in this category. They are recognized only when all instructions prior to the instruction causing one of these exceptions appear to have completed and that instruction is the next instruction to be executed. The two exceptions are mutually exclusive.

The priority of these exceptions is specified for completeness and to ensure that they are not given more favorable treatment. It is acceptable for an implementation to treat these exceptions as though they had a lower priority.

4. Program - Imprecise Mode Floating-Point Enabled Exception

This exception is the fourth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

5. Hypervisor Maintenance

This exception is the fifth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

If a Hypervisor Maintenance exception exists and each attempt to execute an instruction when the Hypervisor Maintenance interrupt is enabled causes an exception (see the Programming Note below), the Hypervisor Maintenance interrupt is not delayed indefinitely.

If LPES=1 and a Direct External exception exists and each attempt to execute an instruction when this interrupt is enabled causes an exception (see the Programming Note below), the Direct External interrupt is not delayed indefinitely.

6.9 Relationship of Event-Based Branches to Interrupts

Event-based exceptions have a priority lower than all exceptions that cause interrupts. When an event-based exception is created, the Event-Based Branch facility waits for all other possible exceptions that would cause interrupts to be reported. It then generates the event-based branch if no exception that would cause an interrupt exists when the event-based branch is to be generated.

---

Programming Note

An incorrect or malicious operating system could corrupt the first instruction in the interrupt vector location for an instruction-caused interrupt such that the attempt to execute the instruction causes the same exception that caused the interrupt (a looping interrupt; e.g., Trap instruction and Program interrupt). Similarly, the first instruction of the interrupt vector for one instruction-caused interrupt could cause a different instruction-caused interrupt, and the first instruction of the interrupt vector for the second instruction-caused interrupt could cause the first instruction-caused interrupt (e.g., Program interrupt and Floating-Point Unavailable interrupt). Similarly, if the Real Mode Area is virtualized and there is no PTE for the page containing the interrupt vectors, every attempt to execute the first instruction of the OS's Instruction Storage interrupt handler would cause a Hypervisor Instruction Storage interrupt; if the Hypervisor Instruction Storage interrupt handler returns to the OS’s Instruction Storage interrupt handler without the relevant PTE having been created, another Hypervisor Instruction Storage interrupt would occur immediately. The looping caused by these and similar cases is terminated by the occurrence of a System Reset or Hypervisor Decrementer interrupt.
Chapter 7. Timer Facilities

7.1 Overview

The Time Base, Decrementer, Hypervisor Decrementer, Processor Utilization of Resources, and Scaled Processor Utilization of Resources registers provide timing functions for the system. The remainder of this section describes these registers and related facilities.

7.2 Time Base (TB)

The Time Base (TB) is a 64-bit register (see Figure 53) containing a 64-bit unsigned integer that is incremented periodically.

![Figure 53. Time Base](image)

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TBU40</td>
<td>Upper 40 bits of Time Base</td>
</tr>
<tr>
<td>TBU</td>
<td>Upper 32 bits of Time Base</td>
</tr>
<tr>
<td>TBL</td>
<td>Lower 32 bits of Time Base</td>
</tr>
</tbody>
</table>

Implementations must provide a means for either preventing the Time Base from incrementing or preventing it from being read in problem state (MSRPR=1). If the means is under software control, it must be privileged and, in implementations of the Server environment, must be accessible only in hypervisor state (MSRHVPRI = 0b10). There must be a method for getting all Time Bases in the system to start incrementing with values that are identical or almost identical.

2. Copying the contents of a GPR to the Time Base replaces the contents of the Time Base with the contents of the GPR.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock in a Power ISA system. The Time Base update frequency is not required to be constant. What is required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

See Chapter 6 of Book II for information about the update frequency of the Time Base.

The Time Base is implemented such that:

1. Loading a GPR from the Time Base has no effect on the accuracy of the Time Base.
7.2.1 Writing the Time Base

Writing the Time Base is privileged, and can be done only in hypervisor state. Reading the Time Base is not privileged; it is discussed in Chapter 6 of Book II.

It is not possible to write the entire 64-bit Time Base using a single instruction. The `mttbl` and `mttbu` extended mnemonics write the lower and upper halves of the Time Base (TBL and TBU), respectively, preserving the other half. These are extended mnemonics for the `mtspr` instruction; see Appendix A, “Assembler Extended Mnemonics” on page 1015.

The Time Base can be written by a sequence such as:

```
lwz     Rx,upper # load 64-bit value for
lwx     Ry,lower # TB into Rx and Ry
li      Rz,0
mttbl   Rx  # set TBL to 0
mttbu   Rx  # set TBU
mttbl   Ry  # set TBL
```

Provided that no interrupts occur while the last three instructions are being executed, loading 0 into TBL prevents the possibility of a carry from TBL to TBU while the Time Base is being initialized.

The preferred method of changing the Time Base utilizes the TBU40 facility. The following code sequence demonstrates the process. Assume the upper 40 bits of

```
lwz Ry,upper # load 64-bit Time Base value
clrldi Ry,Ry,40# lower 24 bits of old TB
mttbu40 Rx # write upper 40 bits of TB
mttb Rz  # read TB value again
clrldi Rz,Rz,40# lower 24 bits of new TB
cmpeq Rz,Ry # compare new and old lwr 24
bge done  # no carry out of low 24 bits
addis Rx,Rx,0x0100#increment upper 40 bits
mttbu40 Rx # update to adjust for carry
```

7.3 Virtual Time Base

The Virtual Time Base (VTB) is a 64-bit incrementing counter.

![Figure 54. Virtual Time Base](image)

The Virtual Time Base increments at the same rate as the Time Base until its value becomes 0xFFFF_FFFF_FFFF_FFFF (2^64 - 1); at the next increment its value becomes 0x0000_0000_0000_0000. There is no interrupt or other indication when this occurs.

The operation of the Virtual Time Base has the following additional properties.

1. Loading a GPR from the Virtual Time Base has no effect on the accuracy of the Virtual Time Base.
2. Copying the contents of a GPR to the Virtual Time Base replaces the contents of the Virtual Time Base with the contents of the GPR.

In systems that change the Time Base update frequency for purposes such as power management, the Virtual Time Base input frequency will also change. Software must be aware of this in order to set interval timers.
7.4 Decrementer

The Decrementer (DEC) is a 32-bit decrementing counter that provides a mechanism for causing a Decrementer interrupt after a programmable delay. The contents of the Decrementer are treated as a signed integer.

The Decrementer counts down until its value becomes 0x0000_0000; at the next decrement its value becomes 0xFFFF_FFFF.

The Decrementer is driven at the same frequency as the Time Base.

When the contents of DEC32 change from 0 to 1, a Decrementer exception will come into existence within a reasonable period of time.

When the contents of DEC32 change from 1 to 0, the existing Decrementer exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DEC32 is the result of decrementation of the Decrementer by the hardware or of modification of the Decrementer caused by execution of an mtspr instruction.

The operation of the Decrementer has the following additional properties.

1. Loading a GPR from the Decrementer has no effect on the accuracy of the Time Base.
2. Copying the contents of a GPR to the Decrementer replaces the contents of the Decrementer with the contents of the GPR.

7.5 Hypervisor Decrementer

The Hypervisor Decrementer (HDEC) is a 32-bit decrementing counter that provides a mechanism for causing a Hypervisor Decrementer interrupt after a programmable delay. The contents of the Hypervisor Decrementer are treated as a signed integer.

In systems that change the Time Base update frequency for purposes such as power management, the Decrementer input frequency will also change. Software must be aware of this in order to set interval timers.

If Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.

### Programming Note

In configurations in which the hypervisor allows multiple partitions to time-share a processor, the Virtual Time Base can be managed by the hypervisor such that it appears to each partition as if it counts only during the times that the partition is executing.

In order to do this, the hypervisor saves the value of the Virtual Time Base as part of the program context when removing a partition from the processor, and restores it to it's previous value when initiating the partition again on the same or another processor.
menter interrupt occurs, the existing Hypervisor Decrementer exception will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event. Even if multiple HDEC32 transitions from 0 to 1 occur before a Hypervisor Decrementer interrupt occurs, at most one Hypervisor Decrementer exception exists.

The preceding paragraph applies regardless of whether the change in the contents of HDEC32 is the result of decrementation of the Hypervisor Decrementer by the hardware or of modification of the Hypervisor Decrementer caused by execution of an mtspr instruction.

The operation of the Hypervisor Decrementer has the following additional properties.

1. Loading a GPR from the Hypervisor Decrementer has no effect on the accuracy of the Hypervisor Decrementer.

2. Copying the contents of a GPR to the Hypervisor Decrementer replaces the contents of the Hypervisor Decrementer with the contents of the GPR.

---

**Programming Note**

In systems that change the Time Base update frequency for purposes such as power management, the Hypervisor Decrementer update frequency will also change. Software must be aware of this in order to set interval timers.

If Hypervisor Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.

---

**Programming Note**

A Hypervisor Decrementer exception is not created if the thread is in a power-saving mode when HDEC32 changes from 0 to 1 because having a Hypervisor Decrementer interrupt occur almost immediately after exiting the power-saving mode in this case is deemed unnecessary. The hypervisor already has control, and if a timed exit from the power-saving mode is necessary and possible, the hypervisor can use the Decrementer to exit the power-saving mode at the appropriate time. For sleep and rwalk power-saving levels, the state of the Hypervisor Decrementer and Decrementer is not necessarily maintained and updated.

---

### 7.6 Processor Utilization of Resources Register (PURR)

The Processor Utilization of Resources Register (PURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the PURR are treated as a 64-bit unsigned integer.

<table>
<thead>
<tr>
<th>PURR</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>63</td>
</tr>
</tbody>
</table>

**Figure 57. Processor Utilization of Resources Register**

The PURR is a hypervisor resource; see Chapter 2.

The contents of the PURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed 0xFFFF_FFFF_FFFF_FFFF (2^64 - 1) at which point the contents are replaced by that sum modulo 2^64. There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the PURR increases is an estimate of the portion of resources used by the thread per unit time with respect to other threads that share those resources monitored by the PURR. When the thread is idle, the rate at which the PURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times T_a and T_b be T_{ab}. Let the difference between the value represented by the contents of the PURR at time T_a and T_b be the value P_{ab}. The ratio of P_{ab}/T_{ab} is an estimate of the percentage of shared resources used by the thread during the interval T_{ab}. For the set (S) of threads that share the resources monitored by the PURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads S, the shared resources corresponding to the set S, and specifics of the algorithm for incrementing the PURR are implementation-specific.

The PURR is implemented such that:

1. Loading a GPR from the PURR has no effect on the accuracy of the PURR.

2. Copying the contents of a GPR to the PURR replaces the contents of the PURR with the contents of the GPR.
7.7 Scaled Processor Utilization of Resources Register (SPURR)

The Scaled Processor Utilization of Resources Register (SPURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the SPURR are treated as a 64-bit unsigned integer.

![Figure 58. Scaled Processor Utilization of Resources Register](image)

The SPURR is a hypervisor resource; see Section 2.7.

The contents of the SPURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed 0xFFFF_FFFF_FFFF_FFFF (2^64 - 1) at which point the contents are replaced by that sum modulo 2^64. There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the SPURR increases is an estimate of the portion of resources used by the thread with respect to other threads that share those resources monitored by the SPURR, and relative to the computational capacity provided by those resources. The computational capacity provided by the shared resources may vary as a function of the frequency of the oscillator which drives the resources or as a result of deliberate delays in processing that are created to reduce power consumption. When the thread is idle, the rate at which the SPURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times T_a and T_b be the value S_{ab}. The ratio of S_{ab}/(T_{ab} \times f_e \times (1 - c_r)) is an estimate of the percentage of shared resource capacity used by the thread during the interval T_{ab}. For the set \{S\} of threads that share the resources monitored by the SPURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads S, the shared resources corresponding to the set S, and specifics of the algorithm for incrementing the SPURR are implementation-specific.

The SPURR is implemented such that:

1. Loading a GPR from the SPURR has no effect on the accuracy of the SPURR.
2. Copying the contents of a GPR to the SPURR replaces the contents of the SPURR with the contents of the GPR.

![Programming Note](image)

Estimates computed as described above may be useful for purposes of resource use accounting, program dispatching, etc.

7.8 Instruction Counter

The Instruction Counter (IC) is a 64-bit incrementing counter that counts the number of instructions that the thread has completed (according to the sequential execution model; see Chapter 2.2 of Book I).

![Figure 59. Instruction Counter](image)
Chapter 8. Debug Facilities

8.1 Overview

Implementations provide debug facilities to enable hardware and software debug functions, such as control flow tracing, data address watchpoints, and program single-stepping. The debug facilities described in this section consist of the Come-From Address Register (see Section 8.1.1), Completed Instruction Address Breakpoint Register (see Section 8.1.2), and the Data Address Watchpoint Register (DAWRn) and Data Address Watchpoint Register Extension (DAWRXn) (see Section 8.1.3). The interrupt associated with the Data Address Breakpoint registers is described in Section 6.5.3. The interrupt associated with the Completed Instruction Address Breakpoint Register is described in Section 6.5.15. The Trace facility, which can be used for single-stepping as well as for control flow tracing, is described in Section 6.5.15.

The mfspr and mtspw instructions (see Section 4.4.4) provide access to the registers of the debug facilities. In addition to the facilities mentioned above, implementations typically provide debug facilities, modes, and access mechanisms that are implementation-specific. For example, implementations typically provide facilities for instruction address tracing, and also access to certain debug facilities via a dedicated interface such as the IEEE 1149.1 Test Access Port (JTAG).

8.1.1 Come-From Address Register

The Come-From Address Register (CFAR) is a 64-bit register. When an rfebb, rfid, instruction is executed, the register is set to the effective address of the instruction. When a Branch instruction is executed and the branch is taken, the register is set to the effective address of an instruction in the instruction cache block containing the Branch instruction, except that if the Branch instruction is a B-form Branch (i.e. bc, bca, bcl, or bcla) for which the target address is in the instruction cache block containing the Branch instruction or is in the previous or next cache block, the register is not necessarily set. For Branch instructions, the setting need not occur until a subsequent context synchronizing operation has occurred.

Figure 60. Come-From Address Register

The contents of the CFAR can be read and written using the mfspr and mtspw instructions. Access to the CFAR is privileged.

Programming Note

This register can be used for purposes of debugging software. For example, often a software bug results in the program executing a portion of the code that it should not have reached or causing an unexpected interrupt. In the former case, a breakpoint can be placed in the portion of the code that was erroneously reached and the program reexecuted. In either case, the interrupt handler can save the contents of the CFAR (before executing the first instruction that would modify the register), and then make the saved contents available for a debugger to use in determining the control flow path by which the exception was reached.

In order to preserve the CFAR's contents for each partition and to prevent it from being used to implement a "covert channel" between partitions, the hypervisor should initialize/save/restore the CFAR when switching partitions on a given thread.

8.1.2 Completed Instruction Address Breakpoint [Category: Trace]

The Completed Instruction Address Breakpoint mechanism provides a means of detecting an instruction completion at a specific instruction address. The address comparison is done on an effective address (EA).

The Completed Instruction Address Breakpoint mechanism is controlled by the Completed Instruction
Address Breakpoint Register (CIABR), shown in Figure 62.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:61</td>
<td>CIEA</td>
<td>Completed Instruction Effective Address</td>
</tr>
<tr>
<td>62:63</td>
<td>PRIV</td>
<td>Privilege</td>
</tr>
</tbody>
</table>

In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A Completed Instruction Address Breakpoint match causes a Trace exception provided that no higher priority interrupt occurs from the completion of the instruction (see Section 6.5.15).

8.1.3 Data Address Watchpoint

The Data Address Watchpoint mechanism provides a means of detecting load and store accesses to a range of addresses starting at a designated doubleword. The address comparison is done on an effective address (EA).

The Data Address Watchpoint mechanism is controlled by a single set of SPRs, numbered with n=0: the Data Address Watchpoint Register (DAWRn), shown in Figure 62, and the Data Address Watchpoint Register Extension (DAWRXn), shown in Figure 63.

<table>
<thead>
<tr>

<tr>
<td>62</td>
<td>PNH</td>
<td>Privileged but Non-Hypervisor state</td>
</tr>
<tr>
<td>63</td>
<td>PRO</td>
<td>Problem state</td>
</tr>
</tbody>
</table>

All other fields are reserved.

The supported PRIVM values are 0b000, 0b001, 0b101, and 0b110. If the PRIVM field does not contain one of the supported values, then whether a match occurs for a given storage access is undefined. Elsewhere in this section it is assumed that the PRIVM field contains one of the supported values.

--- Architecture Note ---

Future versions of the architecture may allow n to be nonzero, thus providing more Data Address Watchpoints. The SPR numbers for DAWRn and DAWRXn have been defined to support this possible future expansion.

--- Programming Note ---

PRIVM value 0b000 causes matches not to occur regardless of the contents of other DAWRn and DAWRXn fields. PRIVM values 0b101 and 0b110 are not supported because a storage location that is shared between the hypervisor and non-hypervisor software is unlikely to be accessed using the same EA by both the hypervisor and the non-hypervisor software. (PRIVM value 0b111 is supported primarily for reasons of software compatibility with respect to emulation of the DABR facility as described in a subsequent Programming Note.)

A Data Address Watchpoint match occurs for a Load or Store instruction if, for any byte accessed, all of the following conditions are satisfied.

- the access is
a quadword access and located in the range
\((DEAW_0:59 \ || \ 0) \leq (EA_0:59 \ || 0) \leq ((DEAW_0:59 \ || 0) + (550 \ || MRD_0:5)))\) such that
\((EA_0:60 \ AND (551 \ || 60)) = (DEAW_0:60 \ AND (551 \ || 60)).\)
- not a quadword access and located in the range \(DEAW_0:60 \leq EA_0:60 \leq (DEAW_0:60 + (550 \ || MRD_0:5)))\) such that
\((EA_0:60 \ AND (551 \ || 60)) = (DEAW_0:60 \ AND (551 \ || 60)).\)
- \((MSR_{DR} = DAWRX_nVT) \ | \ DAWRXnWTI\)
- the thread is in
  - hypervisor state and DAWRXnHYP = 1, or
  - privileged but non-hypervisor state and DAWRXnPHN = 1, or
  - problem state and DAWRXnPR = 1
- the instruction is a \textit{Store} and DAWRXnDW = 1, or
  the instruction is a \textit{Load} and DAWRXnDR = 1.

In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

If the above conditions are satisfied, a match also occurs for \textit{eciw} and \textit{ecow}. For the purpose of determining whether a match occurs, \textit{eciw} is treated as a \textit{Load}, and \textit{ecow} is treated as a \textit{Store}.

If the above conditions are satisfied, it is undefined whether a match occurs in the following cases.

- The instruction is \textit{Store Conditional} but the store is not performed
- The instruction is \textit{dcbz}. (For the purpose of determining whether a match occurs, \textit{dcbz} is treated as a \textit{Store}.)

The \textit{Cache Management} instructions other than \textit{dcbz} never cause a match.

A Data Address Watchpoint match causes a Data Storage exception or a Hypervisor Data Storage exception (see Section 6.5.3, “Data Storage Interrupt” on page 955 and Section 6.5.16, “Hypervisor Data Storage Interrupt” on page 963). If a match occurs, some or all of the bytes of the storage operand may have been accessed; however, if a \textit{Store} or \textit{ecow} instruction causes the match, the storage operand is not modified if the instruction is one of the following:
- any \textit{Store} instruction that causes an atomic access
- \textit{ecow}

**Architecture Note**

For a quadword access, it is possible that the address reported in the DAR/HDAR can point to a byte outside of the range of the watchpoint if the starting address of the watchpoint is not quadword aligned.

**Programming Note**

The Data Address Watchpoint mechanism does not apply to instruction fetches.

**Architecture Note**

For a quadword access, it is possible that the address reported in the DAR/HDAR can point to a byte outside of the range of the watchpoint if the starting address of the watchpoint is not quadword aligned.

**Programming Note**

Implementations that comply with versions of the architecture that precede Version 2.02 do not provide the DABRX (now replaced by DAWRXn). Forward compatibility for software that was written for such implementations (and uses the Data Address Breakpoint facility) can be obtained by setting DAWRXn60:63 to 0b0111.
Chapter 9. Performance Monitor Facility

9.1 Overview

The Performance Monitor facility provides a means of collecting information about program and system performance.

9.2 Performance Monitor Operation

The Performance Monitor facility is controlled by the following features (described in detail in subsequent sections).

- an MSR bit
  - PMM (Performance Monitor Mark), which can be used to select one or more programs for monitoring

- registers
  - PMC1 - PMC6 (Performance Monitor Counters 1 - 6), which count events
  - MMCR0, MMCR1, MMCR2, and MMCRA (Monitor Mode Control Registers 0, 1, 2, and A), which control the Performance Monitor facility
  - SIAR, SDAR, and SIER (Sampled Instruction Address Register, Sampled Data Address Register, and Sampled Instruction Event Register), which contain the address of the “sampled instruction” and of the “sampled data,” and additional information about the “sampled instruction” (see Section 9.4.8 - Section 9.4.10).

- The Branch History Rolling Buffer (BHRB), which is a buffer that contains the target addresses of most recent branch instructions for which the branch was taken.

- the performance monitor interrupt, which can be caused by monitored conditions and events.

Many aspects of the operation of the Performance Monitor are summarized by the following hierarchy, which is described starting at the lowest level.

- A “counter negative condition” exists when the value in a PMC is negative (i.e., when bit 0 of the PMC is 1). A “Time Base transition event” occurs when a selected bit of the Time Base changes from 0 to 1 (the bit is selected by a field in MMCR0). The term “condition or event” is used as an abbreviation for “counter negative condition or Time Base transition event”. A condition or event can be caused implicitly by the hardware (e.g., incrementing a PMC) or explicitly by software (mtpsr).

- A condition or event is enabled if the corresponding “Enable” bit (i.e. PMC1CE, PMCjCE, or TBEE) in MMCR0 is 1. The occurrence of an enabled condition or event can have side effects within the Performance Monitor, such as causing the PMCs to cease counting.

- An enabled condition or event causes a Performance Monitor alert if Performance Monitor alerts are enabled by the corresponding “Enable” bit in MMCR0. A single Performance Monitor alert may reflect multiple enabled conditions and events.

- When a Performance Monitor alert occurs, MMCR0PMAS is set to 1 and the writing of BHRB entries, if in process, is suspended.

  When the contents of MMCR0PMAS change from 0 to 1, a Performance Monitor exception will come into existence within a reasonable period of time. When the contents of MMCR0PMAS change from 1 to 0, the existing Performance Monitor exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

- A Performance Monitor exception causes one of the following.
  - If MSR_CEE = 1 and MMCR0EBE = 0, an interrupt occurs.
  - If MSR_CEE = 1, MMCR0EBE = 1, a Performance Monitor event-based exception occurs if BESC- CPRME=1, provided FSCREBB and HFSCREBB are enabled. When a Performance Monitor event-based exception occurs,
an event-based branch is generated if BES-CRGE=1.

**Programming Note**
The Performance Monitor can be effectively disabled (i.e., put into a state in which Performance Monitor SPRs are not altered and Performance Monitor exceptions do not occur) by setting MMCR0 to 0x0000_0000_8000_0000.

### 9.3 Probe No-op Instruction

A probe no-op is an `and 0,0,0` instruction. This form of `and` is reserved for use exclusively by the Performance Monitor.

**Programming Note**
Software can insert probe no-op instructions at various points in a program and configure the performance monitor such that the instruction is eligible for sampling. See Section 9.4.7.

### 9.4 Performance Monitor Facility Registers

The Performance Monitor registers count events, control the operation of the Performance Monitor, and provide associated information.

The elapsed time between the execution of an instruction and the time at which events due to that instruction have been reflected in Performance Monitor registers is not defined. No means are provided by which software can ensure that all events due to preceding instructions have been reflected in Performance Monitor registers. Similarly, if the events being monitored may be caused by operations that are performed out-of-order, no means are provided by which software can prevent such events due to subsequent instructions from being reflected in Performance Monitor registers. Thus the contents obtained by reading a Performance Monitor register may not be precise: it may fail to reflect some events due to instructions that precede the `mfspr` and may reflect some events due to instructions that follow the `mfspr`. This lack of precision applies regardless of whether the state of the thread is such that the register is subject to change by the hardware at the time the `mfspr` is executed. Similarly, if an `mfspr` instruction is executed that changes the contents of the Time Base, the change is not guaranteed to have taken effect until after a subsequent context synchronizing instruction has been executed.

If an `mfspr` instruction is executed that changes the value of a Performance Monitor register other than SIAR, SDAR, and SIER, the change is not guaranteed to have taken effect until after a subsequent context synchronizing instruction has been executed (see Chapter 12. “Synchronization Requirements for Context Alterations” on page 1009).

**Programming Note**
Depending on the events being monitored, the contents of Performance Monitor registers may be affected by aspects of the runtime environment (e.g., cache contents) that are not directly attributable to the programs being monitored.

#### 9.4.1 Performance Monitor SPR Numbers

The Performance Monitor registers have two sets of SPR numbers, one set that is non-privileged and another set that is privileged.

For the purpose of explanation elsewhere in the architecture, the non-privileged registers are divided into two groups as defined below.

- **A**: The non-privileged read/write Performance Monitor registers (i.e. the PMCs, MMCR0, MMCR2, and MMCRA at SPR numbers 771-776, 779, 769, and 770, respectively)
- **B**: The non-privileged read-only Performance Monitor registers (i.e. SIER, SIAR, SDAR, and MMCR1 at SPR numbers 768, 780, 781, and 782, respectively).

The SPRs in group B are treated as not implemented registers for write (`mtspr`) operations. See the `mtspr` instruction description in Section 4.4.4 for additional information.

When the PCR makes a register in either group A or B unavailable in problem state, that SPR is not included in group A or B.

#### 9.4.2 Performance Monitor Counters

The six Performance Monitor Counters, PMC1 through PMC6, are 32-bit registers that count events.

![Performance Monitor Counter registers](image)

**Figure 64. Performance Monitor Counter registers**

PMC1 - PMC4 are referred to as “programmable” counters since the events that can be counted can be...
specified by the program. The codes that identify the events that are counted are selected by specifying the appropriate code in “PMCn Selector” fields in MMCR1. Some events may include operations that are performed out-of-order.

PMC5 and PMC6 are not programmable. PMC5 counts instructions completed and PMC6 counts cycles. The PMCC field in MMCR0 control whether or not PMCs 5-6 are under the control of various bits in MMCR0 and MMCR2. When PMCs 5-6 are not under the control of these bits, they do not cause performance monitor events.

Normally each PMC is incremented each hardware cycle by the number of times the corresponding event occurred in that cycle. Other modes of incrementing may also be provided.

**Programming Note**

PMC5 and PMC6 are defined to facilitate calculating basic performance metrics such as cycles per instruction (CPI).

Software can use a PMC to “pace” the collection of Performance Monitor data. For example, if it is desired to collect event counts every n cycles, software can specify that a particular PMC count cycles and set that PMC to 0x8000_0000 - n. The events of interest would be counted in other PMCs. The counter negative condition that will occur after n cycles can, with the appropriate setting of MMCR bits, cause counter values to become frozen, cause a Performance Monitor exception to occur, etc.

### 9.4.3 Threshold Event Counter

The threshold event counter and associated controls are in MMCRA (see Section 9.4.7). When the Performance Monitor is enabled (MMCR0PMAE=1), this counter begins incrementing from value 0 upon each occurrence of the event specified in the Threshold Event (TEV) field after recognizing the event specified by the Threshold Start (TS) field. The counter stops incrementing when the event specified in the Threshold End (TE) field occurs. The counter subsequently freezes until the event specified in the TS is again recognized, at which point it increments as explained above. Incrementing stops when a Performance Monitor Alert occurs. After the Performance Monitor alert occurs, the contents of SIAR are not altered by the hardware until software sets MMCR0PMAE to 1.

**Programming Note**

Because hardware can modify the contents of the threshold event counter when random sampling is enabled (MMCRASEM=1) and MMCR0PMAE=1 at any time, any value written to the threshold event counter under this condition may be immediately overwritten by hardware.

The threshold counter value is represented as a base-4 floating-point number. The mantissa of the floating-point number is contained in MMCRA TECM, and the exponent contained in MMCRA TECX. For a given counter mantissa, m, and exponent, e, the number represented is as follows:

\[ N = 4^e \times m \]

This counter format allows the counter to represent a range of 0 through approximately 2M counts with many fewer bits than would be required by a binary counter.

**Programming Note**

Software can obtain the number N from contents of the threshold counter by shifting the mantissa left twice times the value contained in the exponent.

The value in the counter is the exact number of events that occur for values from 0 through the maximum mantissa value (127), within 4 events of the exact value for values from 128 - 508 (or 127^4), within 16 events of the exact value for values from 512 - 2032 (or 127^4^2), and so on. This represents an event count accuracy of approximately 3%, which is expected to be sufficient for most situations in which a count of events between a start and end event is required.

**Programming Note**

When using the threshold counter, software typically specifies a “threshold counter exceeded n” event in MMCR1. This enables a PMC to count the number of times the counter exceeded a specified threshold value during the time Performance Monitor alerts were enabled.

### 9.4.4 Monitor Mode Control Register 0

Monitor Mode Control Register 0 (MMCR0) is a 64-bit register as shown below.

<table>
<thead>
<tr>
<th>MMCR0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>

**Figure 65. Monitor Mode Control Register 0**

Some bits of MMCR0 are altered by the hardware when various events occur, and some bits may be altered by software.
The following notation is used in the definitions below. When MMCR0PMCC = 11, “PMCs” refers to PMCs 1 - 4 and “PMCj” or PMCjCE refers to “PMCj or PMCjCE, respectively, where j = 2 - 4; otherwise, “PMCs” refers to PMCs 1 - 6 and “PMCj” or PMCjCE refers to “PMCj or PMCjCE, respectively, where j = 2 - 6.

When the MMCR0PMCC is set to 10 or 11, providing problem state programs read/write access, only FC, PMAE, PMAO, can be accessed. All other bits are not changed when mtspr is executed in problem state, and all other bits return 0s when mfspr is executed.

**Programming Note**

When PMCC=10 or 11, problem state programs have access to MMCR0 in order to enable event-based branch routines to reset the FC bit after it has been set to 1 as a result of an enabled condition or event (FCECE=1.) During event processing, the event-based branch handler would write the desired initial values to the PMCs and reset the FC bit to 0. PMAO and PMAE can also be set to their appropriate values during the same write operation before returning.

If additional event-based branches are defined in the future, it may be desirable to set PMAE and PMAO using the BESCRS since additional bits in BESCRS will also need to be written.

<tr>
<td>0:31</td>
<td>The PMCs are incremented (if permitted by other MMCR bits) and entries are written into the BHRB (if permitted by the BHRB Instruction Filtering Mode field in MMCRA).</td>
</tr>
</tbody>
</table>

**Programming Note**

In order to freeze counters in problem state regardless of MSRHV, MMCR0FCPC must be set to 0 and MMCR0FCP must be set to 1.

**Freeze Counters while Mark = 1 (FCM1)**

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>35</td>
<td>Freeze Counters while Mark = 1 (FCM1)</td>
</tr>
<tr>
<td>0:31</td>
<td>The PMCs are incremented (if permitted by other MMCR bits).</td>
</tr>
<tr>
<td>1:31</td>
<td>The PMCs are not incremented if MSRPMM=1.</td>
</tr>
</tbody>
</table>

**Freeze Counters while Mark = 0 (FCM0)**

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>36</td>
<td>Freeze Counters while Mark = 0 (FCM0)</td>
</tr>
<tr>
<td>0:31</td>
<td>The PMCs are incremented (if permitted by other MMCR bits).</td>
</tr>
<tr>
<td>1:31</td>
<td>The PMCs are not incremented if MSRPMM=0.</td>
</tr>
</tbody>
</table>

**Performance Monitor Alert Enable (PMAE)**

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Performance Monitor Alert Enable (PMAE)</td>
</tr>
<tr>
<td>0:31</td>
<td>Performance Monitor alerts are disabled and BHRB entries are not written.</td>
</tr>
<tr>
<td>1:31</td>
<td>Performance Monitor alerts are enabled and BHRB entries are written (if enabled by other bits) until a Performance Monitor alert occurs, at which time:</td>
</tr>
<tr>
<td>0:31</td>
<td>MMCR0PMAE is set to 0.</td>
</tr>
<tr>
<td>1:31</td>
<td>MMCR0PMAO is set to 1.</td>
</tr>
</tbody>
</table>

**Programming Note**

Software can set this bit and MMCR0PMAO to 0 to prevent Performance Monitor exceptions.

Software can set this bit to 1 and then poll the bit to determine whether an enabled condition or event has occurred. This is especially useful for software that runs with MSREE=0.

In earlier versions of the architecture that lacked the concept of Performance Monitor alerts, this bit was called Performance Monitor Exception Enable (PMXE).
38 Freeze Counters on Enabled Condition or Event (FCECE)

0 The PMCs are incremented (if permitted by other MMCR bits).
1 The PMCs are incremented (if permitted by other MMCR bits) until an enabled condition or event occurs when MMCR0TRIGGER=0, at which time:
   ■ MMCR0FC is set to 1
If the enabled condition or event occurs when MMCR0TRIGGER=1, the FCECE bit is treated as if it were 0.

39:40 Time Base Selector (TBSEL)

This field selects the Time Base bit that can cause a Time Base transition event (the event occurs when the selected bit changes from 0 to 1).

00 Time Base bit 63 is selected.
01 Time Base bit 55 is selected.
10 Time Base bit 51 is selected.
11 Time Base bit 47 is selected.

Programming Note

Time Base transition events can be used to collect information about activity, as revealed by event counts in PMCs and by addresses in SIAR and SDAR, at periodic intervals.

In multi-threaded systems in which the Time Base registers are synchronized among the threads, Time Base transition events can be used to correlate the Performance Monitor data obtained by the several threads. For this use, software must specify the same TBSEL value for all the threads in the system.

Because the frequency of the Time Base is implementation-dependent, software should invoke a system service program to obtain the frequency before choosing a value for TBSEL.

41 Time Base Event Enable (TBEE)

0 Time Base transition events are disabled.
1 Time Base transition events are enabled.

Programming Note

When PMC3 is configured to count the occurrence of Time Base transition events, the events are counted regardless of the value of MMCR0TBEE. (See Section 9.4.5.) The occurrence of a Time Base transition causes a Performance Monitor alert only if MMCR0TBEE=1.

42 BHRB Access (BHRBA)

This field controls whether the BHRB instructions are available in problem state. If an attempt is made to execute a BHRB instruction is made in problem state when the BHRB instructions are not available, a Facility Unavailable interrupt will occur.

0 mfbhrb and clrbhrb are not available in problem state.
1 mfbhrb and clrbhrb are available in problem state unless they have been made unavailable by some other register.

43 Performance Monitor Event-Based Branch Enable (EBE)

This field controls whether Performance Monitor event-based branches are enabled.

When Performance Monitor event-based branches are disabled, no Performance Monitor event-based branches occur regardless of the state of BESCRPME.

0 Performance Monitor event-based branches are disabled.
1 Performance Monitor event-based branches are enabled.

Programming Note

In order to enable a problem state applications to use the Event-Based Branch facility for Performance Monitor events, privileged software initializes MMCR1 to specify the events to be counted, and sets MMCR2, and MMCRA to specify additional sampling controls. MMCR0 should be initialized with PMCC set to 10 or 11 (to give problem state access to various Performance Monitor registers), PMAE and PMAO set to 0s (disabling Performance Monitor alerts), and EBE set to 1 (enabling event-based branches to occur). If the Event-Based Branch facility has not been enabled in the FSCR and HFSCR, it must be enabled in these registers as well.

The above operations by the operating system enable the application to control Performance Monitor event-based branching by means of BESCRPME (to enable or disable Performance Monitor event-based branching) and MMCR0PMAE (to enable or disable Performance Monitor alerts). The requirement to set both BESCRPME and MMCR0PMAE is not expected to impact application performance since MMCR0PMAE as well as other MMCR0 bits that need to be set can be done in a single mtspr instruction.

44:45 PMC Control (PMCC)
This field controls whether or not PMCs 5 - 6 are included in the Performance Monitor, and the accessibility of groups A and B (see Section 9.4.1) of non-privileged SPRs in problem state as described below.

<table>
<thead>
<tr>
<th></th>
<th>Programming Note</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>PMCs 5 - 6 are included in the Performance Monitor. Group A is read-only in problem state. If an attempt is made to write to an SPR in group A in problem state, a Hypervisor Emulation Assistance interrupt will occur.</td>
</tr>
<tr>
<td>01</td>
<td>PMCs 5 - 6 are included in the Performance Monitor. Group A is not allowed to be read or written in problem state, and group B is not allowed to be read. If an attempt is made to read or write to an SPR in group A, or to read from an SPR in group B in problem state, a Facility Unavailable interrupt will occur.</td>
</tr>
<tr>
<td>10</td>
<td>PMCs 5 - 6 are included in the Performance Monitor. Group A is allowed to be read and written in problem state, and group B except for MMCR1 (SPR 782) is allowed to be read in problem state. If an attempt is made to read MMCR1 in problem state, a Facility Unavailable interrupt will occur.</td>
</tr>
<tr>
<td>11</td>
<td>PMCs 5 - 6 are not included in the Performance Monitor. See Section 9.4.2 for details. Group A except for PMCs 5-6 (SPRs 775,776) is allowed to be read and written, and group B except for MMCR1 (SPR 782) is allowed to be read in problem state. If an attempt is made to read or write to PMCs 5-6 (SPRs 775,776), or to read from MMCR1 in problem state, a Facility Unavailable interrupt will occur. When an SPR is made available by the PMCC field, it is available only if it has not been made unavailable by some other register.</td>
</tr>
</tbody>
</table>

Programming Note

The PMCC field does not affect the behavior of the privileged Performance Monitor Registers (SPRs 784-792, 795-798); accesses to these SPRs in problem state result in Privileged Instruction Type Program interrupts.

The PMCC field also does not affect the behavior of write operations to Group B; write operations to SPRs in Group B are treated as not supported regardless of privilege state. See the mtspr instruction description in Section 4.4.4 for additional information on accessing SPRs that are not supported.

Programming Note

When the PCR makes SPRs unavailable in problem state, they are treated as not implemented, and they are not included in groups A or B regardless of the value of PMCC. Thus when the PCR indicates a version of the architecture prior to V 2.07 (i.e. PCR_{v2.07}=1), the PMCC field does not affect the newly-defined SPRs MMCR2 or SIER; these SPRs are treated as unimplemented registers. Accesses to them in problem state result in Hypervisor Emulation Assistance interrupts regardless of the value of PMCC, and Facility Unavailable interrupts do not occur. See Section 2.6 for additional information.

Freeze Counters in Transactional State (FCTS)

<table>
<thead>
<tr>
<th></th>
<th>Freeze Counters in Non-Transactional State (FCNTS)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>PMCs are incremented (if permitted by other MMCR bits).</td>
</tr>
<tr>
<td>1</td>
<td>PMCs are not incremented when Transactional Memory is in transactional state.</td>
</tr>
</tbody>
</table>
0 PMCs are incremented (if permitted by other MMCR bits).
1 PMCs are not incremented when Transactional Memory is in non-transactional state.

48 **PMC1 Condition Enable (PMC1CE)**
This bit controls whether counter negative conditions due to a negative value in PMC1 are enabled.
0 Counter negative conditions for PMC1 are disabled.
1 Counter negative conditions for PMC1 are enabled.

49 **PMCj Condition Enable (PMCjCE)**
This bit controls whether counter negative conditions due to a negative value in any PMCj (i.e., in any PMC except PMC1) are enabled.
0 Counter negative conditions for all PMCjs except those enabled by PMC1CE, are disabled.
1 Counter negative conditions for all PMCjs are enabled.

50 **Trigger (TRIGGER)**
0 The PMCs are incremented (if permitted by other MMCR bits).
1 PMC1 is incremented (if permitted by other MMCR bits). The PMCs are not incremented until PMC1 is negative or an enabled condition or event occurs, at which time:
- the PMCs resume incrementing (if permitted by other MMCR bits)
- MMCR0\_TRIGGER is set to 0

See the description of the FCECE bit, above, regarding the interaction between TRIGGER and FCECE.

51 **Freeze Counters and BHRB in Problem State Condition (FCPC)**
This bit controls the operation of bit 34 (FCP). See the definition of bit 34 for details.

**Programming Note**
Uses of TRIGGER include the following.
- Resume counting in the PMCjs when PMC1 becomes negative, without causing a Performance Monitor interrupt. Then freeze all PMCs (and optionally cause a Performance Monitor interrupt) when a PMCj becomes negative. The PMCs then reflect the events that occurred between the time PMC1 became negative and the time a PMCj becomes negative. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=0
  - PMCjCE=1
  - TBEE=0
  - FCECE=1
  - PMAE=1 (if a Performance Monitor interrupt is desired)

- Resume counting in the PMCjs when PMC1 becomes negative, and cause a Performance Monitor interrupt without freezing any PMCs. The PMCs then reflect the events that occurred between the time PMC1 became negative and the time the interrupt handler reads them. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=1
  - TBEE=0
  - FCECE=0
  - PMAE=1

52:54 **Performance Monitor Alert Qualifier (PMAOQ)**
These bits provide additional implementation-dependent information about the cause of the Performance Monitor Alert. These bits must be set to 0s when no additional information is available.

55 **Control Counters 5 and 6 With RunLatch (CC56RUN)**
When MMCR0_PMCC = b'11', the setting of this bit has no effect; otherwise it is defined as follows.

0  PMCs 5 and 6 are incremented if CTRL_RUN=1 if permitted by other MMCR bits.
1  PMCs 5 and 6 are incremented, regardless of the value of CTRL_RUN, if permitted by other MMCR bits.

0 The PMCs are incremented (if permitted by other MMCR bits) and BHRB entries are written (if permitted by the BHRB Instruction Filtering Mode field in MMCRa).
1  The PMCs are not incremented and BHRB entries are not written if MSR_HV_PR=0b10.

9.4.5 Monitor Mode Control Register 1

Monitor Mode Control Register 1 (MMCR1) is a 64-bit register as shown below.

```
<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0:31</td>
<td>Problem state access (SPR 782)</td>
</tr>
<tr>
<td>5:6</td>
<td>Privileged access (SPR 782 or 798)</td>
</tr>
<tr>
<td>13</td>
<td>Implementation-dependent</td>
</tr>
</tbody>
</table>
```

Software can set this bit to 1 and set PMAE to 0 to simulate the occurrence of a Performance Monitor alert.

Software should set this bit to 0 after handling the Performance Monitor alert.
### PMC1 Selector (PMC1SEL)

The value of PMC1SEL specifies the event to be counted by PMC 1 as defined below. All values in the range of C0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA<sub>SE</sub>=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA<sub>SM</sub>.)

- **E0**: The thread has dispatched a randomly sampled instruction. (RIS)
- **E2**: The thread has completed a randomly sampled Branch instruction for which the branch was taken. (RIS, RBS)
- **E4**: The thread has failed to locate a randomly sampled instruction in the primary cache. (RIS)
- **E6**: The threshold event counter has exceeded the number of events corresponding to threshold A (see Table 3). (RIS, RLS, RBS)
- **E8**: The threshold event counter has exceeded the number of events corresponding to threshold E (see Table 3). (RIS, RLS, RBS)
- **EA**: The thread filled a block in a cache containing data accessed by a randomly sampled Load instruction. (RIS, RLS)
- **EC**: The threshold event counter has reached its maximum value when random sampling is enabled. (RIS, RLS, RBS)
- **F0**: A cycle has occurred. This event is not controlled by MMCRC<sub>FC1</sub><sub>WAIT</sub>.
- **F2**: A cycle has occurred in which the thread completed one or more instructions.
- **F4**: The thread has completed a Floating Point, Vector Floating Point, or VSX Floating Point instruction other than a load or store operation up to the point at which it has reported all exceptions that it will cause.
- **F6**: The thread has failed to locate an ERAT entry during instruction address translation.
- **F8**: A cycle has occurred in which all previously initiated instructions have completed and no instructions are available for initiation.
- **FA**: A cycle has occurred during which the RUN bit of the control register for one or more threads was set to 1.

### PMC2 Selector (PMC2SEL)

The value of PMC2SEL specifies the event to be counted by PMC 2 as defined below. All values in the range of C0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA<sub>SE</sub>=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA<sub>SM</sub>.)

- **E0**: The thread located the data for a randomly sampled Load instruction from storage that did not reside in any cache. (RIS, RLS)
- **E2**: The thread has failed to locate the data for a randomly sampled Load instruction in the primary data cache. (RIS, RLS)
- **E4**: The thread filled a block in the primary cache containing data accessed by a randomly sampled Load instruction from a location other than the secondary or tertiary cache. (RIS, RLS)
- **E6**: The threshold event counter has exceeded the number of events corresponding to threshold B (see Table 3). (RIS, RLS, RBS)
- **E8**: The threshold event counter has exceeded the number of events corresponding to threshold F (see Table 3). (RIS, RLS, RBS)
- **F0**: A cycle has occurred during which the thread's CTRL register was set to 1.
- **F2**: The thread has dispatched an instruction.
- **F4**: A cycle has occurred during which the thread has completed a Branch instruction for which the branch was taken.
- **F6**: The thread has failed to locate an ERAT entry during data address translation, and a new ERAT entry corresponding to the data address has been written.
- **F8**: An external interrupt for the thread has occurred.
- **FA**: The thread has completed a Branch instruction in the primary cache.
- **FC**: The thread has failed to locate an instruction in the primary cache.
- **FE**: The thread has filled a block in the primary cache containing data accessed by a Load instruction from a location other than the secondary cache.
### PMC3 Selector (PMC3SEL)

The value of PMC3SEL specifies the event to be counted by PMC 3 as defined below. All values in the range of C0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA$_{SE}=1$). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA$_{SM}$.)

- **E2** The thread has completed a randomly sampled *Store* instruction up to the point at which it has reported all exceptions that it will cause. (RIS)
- **E4** The thread has incorrectly predicted the outcome of a randomly sampled *Branch* instruction. (RIS, RBS)
- **E6** The thread has failed to locate a data ERAT entry for a randomly sampled instruction. (RIS)
- **E8** The threshold event counter has exceeded the number of events corresponding to threshold C (see Table 3). (RIS, RLS, RBS)
- **EA** The threshold event counter has exceeded the number of events corresponding to threshold G (see Table 3). (RIS, RLS, RBS)
- **F0** The thread has attempted to store data in the primary cache but the block containing the effective address did not exist.
- **F2** The thread has dispatched an instruction.
- **F4** The thread has completed an instruction during a time when the RUN bit of the CTRL register for all enabled threads on the multi-threaded processor is set to 1.
- **F6** The thread has filled a block in the primary cache with data accessed by a *Load* instruction.
- **F8** A Time Base transition event has occurred for the thread. This event is counted regardless of whether or not Time Base transition events are enabled by MMCRO$_{TBE}$.
- **FA** The thread has loaded an instruction from a higher level cache than the tertiary cache.
- **FC** A thread was unable to translate an effective data address using the TLB.
- **FE** The thread has filled a block in the primary cache containing data accessed by a *Load* instruction with data from a location other than the secondary or tertiary cache.

### PMC4 Selector (PMC4SEL)

The value of PMC4SEL specifies the event to be counted by PMC 4 as defined below. All values in the range of C0 - FF that are not specified below are reserved.

<table>
<thead>
<tr>
<th>Hex</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>Disable events. (No events occur.)</td>
</tr>
<tr>
<td>01-BF</td>
<td>Implementation dependent</td>
</tr>
<tr>
<td>C0-DF</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The following events can occur only when random sampling is enabled (MMCRA$_{SE}=1$). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCRA$_{SM}$.)

- **E0** The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)
- **E4** A thread was unable to translate an effective data address using the TLB. (RIS)
- **E6** The thread has loaded a randomly sampled instruction from a location at a higher level than the tertiary cache. (RIS)
- **E8** The thread filled a block in the primary cache containing data accessed by a randomly sampled *Load* instruction from a location other than the secondary cache. (RIS, RLS)
- **EA** The threshold event counter has exceeded the number of events corresponding to threshold D (see Table 3). (RIS, RLS, RBS)
- **EC** The threshold event counter has exceeded the number of events corresponding to threshold H (see Table 3). (RIS, RLS, RBS)
- **F0** The thread has attempted to load data from the primary cache but the block containing the effective address did not exist.
- **F2** A cycle has occurred in which the thread has dispatched one or more instructions.
- **F4** A cycle has occurred in which the PURR was incremented when the RUN bit of the CTRL register was set to 1.
- **F6** The thread has incorrectly predicted the outcome of a branch instruction.
- **F8** The thread has discarded fetched instructions.
- **FA** The thread has completed an instruction when the RUN bit of the CTRL register is set to 1.
- **FC** A thread was unable to translate an effective instruction address using the TLB and has stored an entry corresponding to the instructions effective address in the TLB.
- **FE** The thread has loaded data for a *Load* instruction from storage that did not reside in any cache.
9.4.6 Monitor Mode Control Register 2

Monitor Mode Control Register 2 (MMCR2) is a 64-bit register that contains 9-bit control fields for controlling the operation of PMC1 - PMC6 as shown below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
<th>0</th>
<th>8</th>

</tbody>
</table>

Figure 67. Monitor Mode Control Register 2

When MMCR0_PMCC = b’11’, fields C1 - C4 control the operation of PMC1 - PMC4, respectively and fields C5 and C6 are meaningless; otherwise, fields C1 - C6 control the operation of PMC1 - PMC6, respectively. The bit definitions of each Cn field are as follows, where n = 1,...,6.

When the MMCR0_PMCC is set to 10 or 11, providing problem state programs read/write access, only the FCnP bits can be accessed. All other bits are not changed when *mtspr* is executed in problem state, and all other bits return 0s when *mfspr* is executed.

Bits 54:63 of MMCR2 are implementation dependent.

9.4.7 Monitor Mode Control Register A

Monitor Mode Control Register A (MMCRA) is a 64-bit register as defined below.

<table>
<thead>
<tr>
<th>Bit</th>

</tbody>
</table>

**Programming Note**

The filters provided by the 10 and 11 values of IFM field can be restated in terms of the operation performed as follows:

00 Do not record the instruction address of any unconditional Branch instruction; record only the target address of XL-form unconditional Branch instructions.

10 Filter as for encoding 10, but for conditional Branch instructions that provide a hint or that do not depend on the value of CRBI, do not record the instruction if it is B-Form and record only the target address if it is XL-Form.

34:36 **Threshold Event Counter Exponent (TECX)**

This field species the exponent of the threshold event counter value. See Section 9.4.3 for additional information. The maximum exponent supported must be at least 5.

37 Reserved

38:44 **Threshold Event Counter Mantissa (TECM)**

This field species the mantissa of the threshold event counter value. See Section 9.4.3 for additional information.

**Programming Note**

Problem state programs need to read the TECX and TECM fields during processing of an event-based branch that occurs due to a “threshold counter exceeded n” event. All the other fields will typically be initialized by the operating system.

45:47 **Threshold Event Counter Event (TECE)**

This field specifies that is counted by the Threshold Event Counter. The values and meanings are specified as follows.

<table>
<thead>
<tr>
<th>Value</th>
<th>Event</th>
</tr>
</thead>
<tbody>
<tr>
<td>000</td>
<td>Disable Counting</td>
</tr>
<tr>
<td>001</td>
<td>A cycle has occurred</td>
</tr>
<tr>
<td>010</td>
<td>An instruction has completed.</td>
</tr>
<tr>
<td>011</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

All other values are implementation-dependent.

48:51 **Threshold Start Event (TS)**

This field specifies the event that causes the threshold event counter to start counting cycles. The events only occur if MMCRA[SE]=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode is specified in MMCRA[SM].) 0000 Reserved.

0001 The thread has randomly sampled an instruction while it is being decoded. (RIS)

0010 The thread has dispatched a randomly sampled instruction. (RIS)

0011 A randomly sampled instruction has been sent to a facility (e.g. Branch, Fixed Point, etc.) (RIS, RLS, RBS)

0100 The thread has completed a randomly sampled instruction up to the point at which it has caused all the exceptions that it will cause. (RIS, RLS, RBS)

0101 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)

0110 The thread has failed to locate data for a randomly sampled Load instruction in the primary data cache. (RIS, RLS)
0111 The thread has filled a block in the primary cache containing data accessed by a randomly sampled Load instruction. (RIS, RLS)

The following values have different definitions for problem state than other privilege states.

Problem state access (SPR 770)
1000 - 1111 - Reserved

Privileged access (SPR 770 or 786)
1000 - 1111 - Implementation-dependent

Threshold End Event (TE)

This field specifies the event that causes the threshold event counter to stop counting cycles. The events only occur if MMCRA\textsubscript{SE}=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode is specified in MMCRA\textsubscript{SM}.)

The following values have different definitions for problem state than other privilege states.

Problem state access (SPR 770)
1000 - 1111 - Reserved

Privileged access (SPR 770 or 786)
1000 - 1111 - Implementation-dependent

Eligibility for Random Sampling (ES)

When random sampling is enabled (SE=1) and the SM field indicates random instruction sampling (RIS), the encodings of this field specify the instructions that are eligible to be sampled as follows.

000 All instructions
001 All Load and Store instructions
010 All probe no-op instructions
011 Reserved.

The following values have different definitions for problem state than other privilege states.

Problem state access (SPR 770)
100 - 111 - Reserved

Privileged access (SPR 770 or 786)
100 - 111 - Implementation-dependent

When random sampling is enabled (SE=1) and the SM field indicates random load/store facility sampling (RLS), the encodings of this field specify the instructions that are eligible to be sampled as follows.

000 Instructions for which the thread has attempted to load data from the cache but the block containing the effective address did not exist.
001 Reserved
010 Reserved
011 Reserved

The following values have different definitions for problem state than other privilege states.

Problem state access (SPR 770)
100 - 111 - Reserved

Privileged access (SPR 770 or 786)
100 - 111 - Implementation-dependent

When random sampling is enabled (ES=1) and the SM field indicates random Branch Facility sampling (RBS), the encodings of this field specify the instructions that are eligible to be sampled as follows.

000 Instructions for which the thread has incorrectly predicted the outcome of a Branch instruction.
001 Instructions for which the thread has incorrectly predicted the outcome of a Branch instruction because the Condition Register was different from the predicted value.
010 Instructions for which the thread has incorrectly predicted the target address of a Branch instruction.
011 All Branch instructions for which the branch was taken.

The following values have different definitions for problem state than other privilege states.

Problem state access (SPR 770)
100 - 111 - Reserved
Privileged access (SPR 770 or 786)
100 - 111 - Implementation-dependent

60 Reserved

61:62 Random Sampling Mode (SM)

00 Random Instruction Sampling (RIS) - Instructions that meet the criterion specified in the ES field for random instruction sampling are eligible to be sampled.

01 Random Load/Store Facility Sampling (RLS) - Instructions that meet the criterion specified in the ES field for random Load/Store Facility sampling are eligible for sampling.

10 Random Branch Facility Sampling (RBS) Instructions that meet the criterion specified in the ES field for random Branch Facility sampling are eligible for sampling.

11 Reserved

63 Random Sample Enable (SE)

0 Continuous sampling is enabled.
1 Random sampling is enabled.

See Section 9.4.8 for information about sampling.

9.4.8 Sampled Instruction Address Register

The Sampled Instruction Address Register (SIAR) is a 64-bit register.

| SIAR | 0 | 63 |

Figure 69. Sampled Instruction Address Register

When a Performance Monitor alert occurs because of an event that occurred due to a randomly sampled instruction, the SIAR contains the effective address of the instruction if SIER_{SIARV} = 1 and is invalid if SIER_{SIARV} = 0.

When a Performance Monitor alert occurs because of an event other than an event that occurred due to a randomly sampled instruction, the SIAR contains the effective address of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred.

The contents of SIAR may be altered by the hardware if and only if MMCR0_{PMAE} = 1. Thus after the Performance Monitor alert occurs, the contents of SIAR are undefined until the next Performance Monitor alert occurs.

Programming Note

If the Performance Monitor alert causes a Performance Monitor interrupt, the value of MSR_{HV PR} that was in effect when the sampled instruction was being executed is reported in SIER.

9.4.9 Sampled Data Address Register

The Sampled Data Address Register (SDAR) is a 64-bit register.

| SDAR | 0 | 63 |

Figure 70. Sampled Data Address Register

When a Performance Monitor alert occurs because of an event that occurred due to a randomly sampled instruction, the SDAR contains the effective address of the data accessed by the instruction if SIER_{SDARV} = 1 and is invalid if SIER_{SDARV} = 0.

When a Performance Monitor alert occurs because of an event other than an event that occurred due to a randomly sampled instruction, the SDAR contains the effective address of the storage operand of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred. This storage operand may or may not be the storage operand (if any) associated with the instruction whose address is in the SIAR.

The contents of SDAR may be altered by the hardware if and only if MMCR0_{PMAE} = 1. Thus after the Performance Monitor alert occurs, the contents of SDAR are not altered by the hardware until software sets MMCR0_{PMAE} to 1. After software sets MMCR0_{PMAE} to 1, the contents of SDAR are undefined until the next Performance Monitor alert occurs.

Programming Note

If the Performance Monitor alert causes a Performance Monitor interrupt, MMCRA indicates whether the sampled data is the storage operand of the sampled instruction.

9.4.10 Sampled Instruction Event Register

The Sampled Instruction Event Register (SIER) is a 64-bit register.

When random sampling is enabled and a Performance Monitor Alert occurs because of an event caused by execution of a randomly sampled instruction, this register contains information about the sampled instruction.
(i.e. the instruction whose effective address is contained in the SIAR) when a Performance Monitor alert occurred. All fields are valid unless otherwise indicated.

**Programming Note**

A Performance Monitor Alert is caused by execution of a randomly sampled instruction if any of the following apply when the Performance Monitor Alert occurs:

- random sampling was enabled and a counter negative condition exists in a PMC that was counting events based on randomly sampled instructions
- a threshold start event was specified in MMCRA and the threshold event counter has reached its maximum value.

When random sampling is disabled or when a Performance Monitor Alert occurs because of an event that was not caused by execution of a randomly sampled instruction, then the contents of this register are meaningless.

**Figure 71. Sampled Instruction Event Register**

The contents of SIER may be altered by the hardware if and only if MMCR0\textsubscript{PMAE}=1. Thus after the Performance Monitor alert occurs, the contents of SIER are not altered by the hardware until software sets MMCR0\textsubscript{PMAE} to 1. After software sets MMCR0\textsubscript{PMAE} to 1, the contents of SIER are undefined until the next Performance Monitor alert occurs.

The bit definitions of the SIER are as follows.

<table>
<thead>
<tr>

101 Reserved.
110 Reserved
111 Reserved

52 **Sampled Instruction Taken Branch** (SITAKBR)
Set to 1 if the SITYPE field indicates a Branch instruction and the branch was taken; otherwise set to 0.

53 **Sampled Instruction Mispredicted Branch** (SIMISPED)
Set to 1 if the SITYPE field indicates a Branch instruction and the thread incorrectly predicted the outcome of the instruction; otherwise set to 0.

54:55 **Sampled Branch Instruction Misprediction Information** (SIMISPREDICT)
If SIMISPRED=1, this field indicates how the thread incorrectly predicted the outcome of a Branch instruction; otherwise this field is set to 0.

56 **Sampled Instruction Data ERAT Miss** (SIDERAT)
When the SITYPE field indicates a Load or Store instruction, this field is set to 1 if the thread has failed to locate an ERAT entry during data address translation for the sampled instruction and otherwise is set to 0.

When the SITYPE field does not indicate a Load or Store instruction, this field is not valid.

57:59 **Sampled Instruction Data Address Translation Information** (SIDAXLATE)
This field contains information about data address translation for the sampled instruction. The values and their meanings are as follows.
000 The instruction did not access data.
001 The thread was able to translate the effective data address using the TLB.
010 A PTEG entry required for data translation for the instruction was loaded from the secondary cache.
011 A PTEG entry required for data translation for the instruction was loaded from the tertiary cache.
100 A PTEG entry required for data translation for the instruction was loaded from storage that did not reside in any cache.
101 A PTEG entry required for data translation for the instruction was loaded from a cache on a different multi-threaded processor that resides on the same chip as the thread.
110 A PTEG entry required for data translation for the instruction was loaded from a cache on a different chip from the thread.
111 Reserved

60:62 **Sampled Instruction Storage Access Information** (SISAI)
This field contains information about storage accesses made by the sampled instruction. The values and their meanings are as follows.
000 The instruction did not access data.
001 The thread was able to access the data referenced by the instruction from the primary cache.
010 The thread was able to access the data referenced by the instruction from the secondary cache.
011 The thread was able to access the data referenced by the instruction from the tertiary cache.
100 The thread was able to access the data referenced by the instruction from storage that did not reside in any cache.
101 The thread was able to access the data referenced by the instruction from a cache on a different multi-threaded processor that resides on the same chip as the thread.
110 The thread was able to access the data referenced by the instruction from a cache on a different chip from the thread.
111 The instruction was a Store for which the data was placed into a location other than the primary cache.

63 **Sampled Instruction Completed** (SICMPL)
Set to 1 if the sampled instruction has completed; otherwise set to 0.
9.5 Branch History Rolling Buffer

The Branch History Rolling Buffer (BHRB) is described in Book I but only at the level required by application programmers. Additional aspects of the BHRB are described here.

In order to enable problem state programs to use the BHRB, MMCR0BHRBA must be set to 1 to enable execution of \texttt{mfbhrb} and \texttt{clrbhrb} instructions in problem state. Additionally, MMCR0EBE must also be set to 1 to enable Performance Monitor event-based branches, and MMCR0PMCC must be set to 10 or 11 to allow problem state programs to access the necessary Performance Monitor registers. (See Section 9.4.4.)

The BHRB is written by the hardware if and only if performance monitor alerts are enabled by setting MMCR0PMAE to 1. After MMCR0PMAE has been set to 1 and a Performance Monitor alert occurs, MMCR0PMAE is set to 0 and the BHRB is not altered by hardware until software sets MMCR0PMAE to 1 again.

When MMCR0PMAE=1, \texttt{mfbhrbe} instructions return 0s to the target register.

BHRB Entries

When the BHRB is written by hardware, only those Branch instructions that meet the filtering criterion indicated by MMCRAIFM and for which the branch was taken are included.

In addition to the mode of BHRB operation described in Book I, an implementation is allowed to provide an implementation-dependent mode of the operation in which the entries that are written are implementation dependent. If such a mode is provided, the means by which the BHRB is put into this mode must be a hypervisor resource.

9.6 Interaction With Other Facilities

9.6.1 Trace Facility

If the Trace facility includes setting SIAR and SDAR (see Section 6.5.15, “Trace Interrupt [Category: Trace]”), and tracing is active (MSRSE=1 or MSRBE=1), the contents of SIAR and SDAR as used by the Performance Monitor facility are undefined and may change even when MMCR0PMAE=0.

---

**Programming Note**

A potential combined use of the Trace and Performance Monitor facilities is to trace the control flow of a program and simultaneously count events for that program.
Chapter 10. External Control [Category: External Control]

The External Control facility permits a program to communicate with a special-purpose device. The facility consists of a Special Purpose Register, called EAR, and two instructions, called External Control In Word Indexed (eciwx) and External Control Out Word Indexed (ecowx).

This facility must provide a means of synchronizing the devices with the hardware to prevent the use of an address by the device when the translation that produced that address is being invalidated.

10.1 External Access Register

This 32-bit Special Purpose Register controls access to the External Control facility and, for external control operations that are permitted, identifies the target device.

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>E</td>
<td>Enable bit</td>
</tr>
<tr>
<td>58:63</td>
<td>RID</td>
<td>Resource ID</td>
</tr>
</tbody>
</table>

All other fields are reserved.

Figure 72. External Access Register

The External Access Register (EAR) is a hypervisor resource; see Chapter 2.

The high-order bits of the RID field that correspond to bits of the Resource ID beyond the width of the Resource ID supported by the implementation are treated as reserved bits.

Programming Note

The hypervisor can use the EAR to control which programs are allowed to execute External Access instructions, when they are allowed to do so, and which devices they are allowed to communicate with using these instructions.

10.2 External Access Instructions

The External Access instructions, External Control In Word Indexed (eciwx) and External Control Out Word Indexed (ecowx), are described in Book II. Additional information about them is given below.

If attempt is made to execute either of these instructions when EAR_E=0, a Data Storage interrupt occurs with bit 43 of the DSISR set to 1.

The instructions are supported whenever MSR_DR=1. If either instruction is executed when MSR_DR=0 (real addressing mode), the results are boundedly undefined.
Chapter 11. Processor Control [Category: Server.Processor Control]

11.1 Overview

The Processor Control facility provides a mechanism for the hypervisor to send messages to other threads that are on the same multi-threaded processor. Privileged programs are able to send messages to other threads on the same multi-threaded processor; if the processor is configured into sub-processors, privileged programs can only send messages to other threads on the same sub-processor.

11.2 Programming Model

Both hypervisor-level and privileged-level messages can be sent. Hypervisor-level messages are sent using the `msgsnd` instruction and cause hypervisor-level exceptions when accepted. Privileged-level messages are sent using the `msgsndp` instruction and cause privileged-level exceptions when accepted. For both instructions, the message type is specified in a general purpose register.

11.2.1 Message Type

The message type is specified by the contents of bits 32:36 in the RB operand of the `msgsnd` or `msgsndp` instruction as follows.

Message type for `msgsnd`

<table>
<thead>
<tr>
<th>RB32:36</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>5</td>
<td>Directed Hypervisor Doorbell Interrupt (DH_DBELL)</td>
</tr>
</tbody>
</table>

A Directed Hypervisor Doorbell exception is generated on a thread only after it has filtered and determined that it should accept the message, and the thread is on the same multi-threaded processor as the thread executing the `msgsnd` instruction.

All other values of RB32:36 are reserved; if the instruction is executed with this field set to a reserved value, the instruction is treated as a no-op.

Message type for `msgsndp`

<table>
<thead>
<tr>
<th>RB32:36</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>5</td>
<td>Directed Privileged Doorbell Interrupt (DP_DBELL)</td>
</tr>
</tbody>
</table>

A Directed Privileged Doorbell exception is generated on a thread only after it has filtered and determined that it should accept the message, and the following are satisfied:

- for processors not partitioned into sub-processors, the thread is on the same multi-threaded processor as the thread executing the `msgsndp` instruction,
- for processors partitioned into sub-processors, the thread is on the same sub-processor as the thread executing the `msgsndp` instruction.

All other values of RB32:36 are reserved; if the instruction is executed with this field set to a reserved value, the instruction is treated as a no-op.

11.2.2 Doorbell Message Payload and Filtering

The message payload is specified by the contents of bits 37:63 in the RB operand of the `msgsnd` or `msgsndp` instruction.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Reserved</td>
</tr>
<tr>
<td>38:56</td>
<td>Reserved</td>
</tr>
<tr>
<td>57:63</td>
<td>TIR Tag (TIRTAG)</td>
</tr>
</tbody>
</table>

For `msgsnd` instructions, the recipient of the message compares this field during the filtering process with its privileged thread number. For `msgsndp` instructions, the recipient of the message compares this field during the filtering process with its hypervisor thread number.
Filtering

The examination of the message payload for the purpose of determining if the message is to be accepted is referred to as filtering.

If a Directed Hypervisor Doorbell message is received by a thread, the message is accepted and the corresponding exception is generated only if the TIRTAG field of the message payload is equal to the hypervisor thread number of the recipient.

If a Directed Privileged Doorbell message is received by a thread, the message is accepted and the corresponding exception is generated only if the TIRTAG field of the message payload is equal to the privileged thread number of the recipient.

If the message is to be accepted, the exception specified by the type field is generated, otherwise the message is ignored. When the exception is generated, the corresponding interrupt occurs when no higher priority exception exists and the interrupt is enabled (MSREEE=1 for the Directed Privileged Doorbell interrupt and MSRE=1 or MSR HV=0 for the Directed Hypervisor Doorbell interrupt).

A Directed Privileged Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a mtsp or msgclrp instruction.

A Directed Hypervisor Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a mtsp or msgclrp instruction.

If a doorbell exception is present and the corresponding interrupt is pended because MSREEE=0, additional doorbell exceptions are ignored until the exception is cleared.

Programming Note

If msgsndp is executed with TIRTAG set to a value greater than the highest privileged thread number on the sub-processor (or on the processor if sub-processors are not supported), then this instruction behaves as a no-op because the filtering process (see below) prevents the receiving threads from accepting it. Similarly, if msgsnd is executed with TIRTAG set to a value greater than the highest hypervisor thread number on the processor, then the instruction also behaves as a no-op.

11.3 Processor Control Registers

11.3.1 Directed Privileged Doorbell Exception State

The layout of the Directed Privileged Doorbell Exception State (DPDES) register is shown in below.

<table>
<thead>
<tr>
<th>DPDES</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>

Figure 73. Directed Privileged Doorbell Exception State Register

The DPDES register is a 64-bit register. For t < T, where T is the number of threads on the sub-processor (or on the multi-threaded processor if sub-processors are not supported), bit 63-t corresponds to the thread with privileged thread number t.

When the contents of DPDES_63-t change from 0 to 1, a Directed Privileged Doorbell exception will come into existence within a reasonable period of time. When the contents of DPDES_63-t change from 1 to 0, the existing Directed Privileged Doorbell exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DPDES_63-t is the result a msgsndp or msgclrp instruction or of modification of the DPDES register caused by execution of an mtsp instruction.

Bits 0:63-T of the DPDES are reserved.

11.3.2 Directed Hypervisor Doorbell Exception State

The layout of the Directed Hypervisor Doorbell Exception State (DPDES) register is shown in below.

<table>
<thead>
<tr>
<th>DHDES</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>

Figure 74. Directed Hypervisor Doorbell Exception State Register

The DHDES register is a 64-bit register. For t < T, where T is the number of threads on the multi-threaded processor, bit 63-t corresponds to the thread with hypervisor thread number t.

When the contents of DHDES_63-t change from 0 to 1, a Directed Hypervisor Doorbell exception will come into existence within a reasonable period of time. When the contents of DHDES_63-t change from 1 to 0, the existing Directed Hypervisor Doorbell exception, if any, will
cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DHDES₆₃₋₁ is the result a \texttt{msgsnd} or \texttt{msgclr} instruction or of modification of the DHDES register caused by execution of an \texttt{mtspr} instruction.

Bits 0:63-T of the DHDES are reserved.
11.4 Processor Control Instructions

`msgsnd`, `msgsndp`, `msgclr`, and `msgclrp` instructions are provided for sending and clearing messages. `msgsnd` and `msgsndp` are privileged instructions, while `msgclr` and `msgclrp` are hypervisor privileged instructions.

### Message Send

#### X-form

```
msgsnd   RB
31 /// /// RB 206 /
```

- `msgtype` ← GPR(RB)_{32:36}
- `payload` ← GPR(RB)_{37:63}
- `t` ← RB_{57:63}
- IF(`msgtype` = 0x05) and `t` ≤ maximum hypervisor thread number on processor
  then
  DHDES_{63-63-t} ← 1
  send_msg(`msgtype`, `payload`)

`msgsnd` sends a message to other threads.

Let `msgtype` be (RB)_{32:36}, let message `payload` be (RB)_{37:63}, and let `t` be the hypervisor thread number of the thread executing the `msgsnd`. If `msgtype` = 0x05 and `t` is less than or equal to the maximum hypervisor thread number on the same multithreaded processor (or sub-processor if sub-processors are supported), then send the Directed Hypervisor Doorbell message to thread `t` on the same multithreaded processor and set DPDES_{63-63-t} to 1.

The actions taken on receipt of a message are defined in Section 11.2.2.

This instruction is hypervisor privileged.

**Special Registers Altered:**

- DHDES

---

**Programming Note**

If `msgsnd` is used to notify the receiver that updates have been made to storage, a `sync` should be placed between the stores and the `msgsnd`. See Section 5.9.2.

### Message Clear

#### X-form

```
msgclr   RB
31 /// /// RB 238 /
```

- `msgtype` ← (RB)_{32:36}
- IF(`msgtype` = 0x05)
  then
  `t` ← hypervisor thread number of executing thread
  DHDES_{63-t} ← 0

`msgclr` clears a message of `msgtype` previously accepted by the thread executing the `msgclr`.

Let `msgtype` be (RB)_{32:36}, and let `t` be the hypervisor thread number of the thread executing the `msgclr`. If `msgtype` = 0x05, then clear any exception that exists for this message type by setting DHDES_{63-t} to 0; otherwise do not modify DHDES or clear any exceptions for this message.

Execution of `msgclr` ensures that the formerly pending exception will not result in an interrupt when the corresponding interrupt class is reenabled.

The types of messages that can be cleared are defined in Section 11.2.1.

This instruction is hypervisor privileged.

**Special Registers Altered:**

- DHDES

---

**Programming Note**

`msgclr` is typically issued only when MSR_{EE}=0. If `msgclr` is executed when MSR_{EE}=1 when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.
**Message Send Privileged X-form**

<table>
<thead>
<tr>
<th>msgsndp</th>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>RB</td>
<td>31</td>
</tr>
</tbody>
</table>

msgtype ← GPR(RB)_{32:36}
payload ← GPR(RB)_{37:63}
t ← RB_{57:63}
IF(msgtype = 0x05) and
  t ≤ maximum privileged thread number
  on processor or sub-processor
  then
  DPDES_{63-t} ← 1
  send_msg(msgtype, payload)

**msgsndp** sends a message to other threads.

Let msgtype be (RB)_{32:36}, let message payload be (RB_{37:63}), and let t be the privileged thread number indicated in RB_{57:63}. If msgtype = 0x05 and t is less than or equal to the maximum privileged thread number on the multi-threaded processor (or on the sub-processor if sub-processors are supported), then send the Directed Privileged Doorbell message to thread t on the same multithreaded processor (or sub-processor if sub-processors are supported), and set DPDES_{63-t} to 1.

The actions taken on receipt of a message are defined in Section 11.2.2.

This instruction is privileged.

**Special Registers Altered:**

DPDES

---

**Programming Note**

If **msgsndp** is used to notify the receiver that updates have been made to storage, a sync should be placed between the stores and the **msgsnd**. See Section 5.9.2.

**Message Clear Privileged X-form**

<table>
<thead>
<tr>
<th>msgclrp</th>
<th>RB</th>
</tr>
</thead>
<tbody>
<tr>
<td>RB</td>
<td>31</td>
</tr>
</tbody>
</table>

msgtype ← (RB)_{32:36}
IF(msgtype = 0x05)
  then
  t ← privileged thread number of executing thread
  DPDES_{63-t} ← 0

**msgclrp** clears a message of msgtype previously accepted by the thread executing the **msgclrp**.

Let msgtype be (RB)_{32:36}, and let t be the thread number of the thread executing the **msgclrp**. If msgtype = 0x05, then clear any exception that exists for this message type by setting DPDES_{63-t} to 0; otherwise do not modify DPDES or clear any exceptions for this message.

Execution of **msgclrp** ensures that the formerly pending exception will not result in an interrupt when the corresponding interrupt class is reenabled.

The types of messages that can be cleared are defined in Section 11.2.1.

This instruction is privileged.

**Special Registers Altered:**

DPDES

---

**Programming Note**

**msgclrp** is typically issued only when MSR_{EE}=0. If **msgclrp** is executed when MSR_{EE}=1 when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.
Chapter 12. Synchronization Requirements for Context Alterations

Changing the contents of certain System Registers, the contents of SLB entries, or the contents of other system resources that control the context in which a program executes can have the side effect of altering the context in which data addresses and instruction addresses are interpreted, and in which instructions are executed and data accesses are performed. For example, changing MSRIR from 0 to 1 has the side effect of enabling translation of instruction addresses. These side effects need not occur in program order, and therefore may require explicit synchronization by software. (Program order is defined in Book II.)

An instruction that alters the context in which data addresses or instruction addresses are interpreted, or in which instructions are executed or data accesses are performed, is called a context-altering instruction. This chapter covers all the context-altering instructions. The software synchronization required for them is shown in Table 4 (for data access) and Table 5 (for instruction fetch and execution).

The notation “CSI” in the tables means any context synchronizing instruction (e.g., sc, isync, or rfid). A context synchronizing interrupt (i.e., any interrupt except non-recoverable System Reset or non-recoverable Machine Check) can be used instead of a context synchronizing instruction. If it is, phrases like “the synchronizing instruction”, below, should be interpreted as meaning the instruction at which the interrupt occurs. If no software synchronization is required before (after) a context-altering instruction, “the synchronizing instruction before (after) the context-altering instruction” should be interpreted as meaning the context-altering instruction itself.

The synchronizing instruction before the context-altering instruction ensures that all instructions up to and including that synchronizing instruction are fetched and executed in the context that existed before the alteration. The synchronizing instruction after the context-altering instruction ensures that all instructions after that synchronizing instruction are fetched and executed in the context established by the alteration. Instructions after the first synchronizing instruction, up to and including the second synchronizing instruction, may be fetched or executed in either context.

If a sequence of instructions contains context-altering instructions and contains no instructions that are affected by any of the context alterations, no software synchronization is required within the sequence.

**Programming Note**

Sometimes advantage can be taken of the fact that certain events, such as interrupts, and certain instructions that occur naturally in the program, such as the rfid that returns from an interrupt handler, provide the required synchronization.

No software synchronization is required before or after a context-altering instruction that is also context synchronizing or when altering the MSR in most cases (see the tables). No software synchronization is required before most of the other alterations shown in Table 5, because all instructions preceding the context-altering instruction are fetched and decoded before the context-altering instruction is executed (the hardware must determine whether any of these preceding instructions are context synchronizing).

Unless otherwise stated, the material in this chapter assumes a single-threaded environment.

Table 5: Synchronization requirements for instruction fetch and/or execution
Notes:

1. The effect of changing the EE bit is immediate, even if the `mtmsr[d]` instruction is not context synchronizing (i.e., even if L=1).
   - If an `mtmsr[d]` instruction sets the EE bit to 0, neither an External interrupt a Decrementer interrupt nor a Performance Monitor interrupt occurs after the `mtmsr[d]` is executed.
   - If an `mtmsr[d]` instruction changes the EE bit from 0 to 1 when an External, Decrementer, Performance Monitor or higher priority exception exists, the corresponding interrupt occurs immediately after the `mtmsr[d]` is executed, and before the next instruction is executed in the program that set EE to 1.
   - If a hypervisor executes the `mtmsr[d]` instruction that sets the EE bit to 0, a Hypervisor Decrementer interrupt does not occur after `mtmsr[d]` is executed as long as the thread remains in hypervisor state.
   - If the hypervisor executes an `mtmsr[d]` instruction that changes the EE bit from 0 to 1 when a Hypervisor Decrementer or higher priority exception exists, the corresponding interrupt occurs immediately after the `mtmsr[d]` instruction is executed, and before the next instruction is executed, provided HDICE is 1.

2. Synchronization requirements for this instruction are implementation-dependent.

3. SDR1 must not be altered when MSR_DR=1 or MSR_IR=1; if it is, the results are undefined.

4. A `ptesync` instruction is required before the `mtspr` instruction because (a) SDR1 identifies the Page Table and thereby the location of Reference and Change bits, and (b) on some implementations, use of SDR1 to update Reference and Change bits may be independent of translating the virtual address. (For example, an implementation might identify the PTE in which to update the Reference and Change bits in terms of its offset in the Page Table, instead of its real address, and then add the Page Table address from SDR1 to the offset to determine the real address at which to update the bits.) To ensure that Reference and Change bits are updated in the correct Page Table, SDR1 must not be altered until all Reference and Change bit updates associated with address translations that were performed, by the thread executing the `mtspr` instruction, before the `mtspr` instruction is executed have been performed with respect to that thread. A `ptesync` instruction guarantees this synchronization of Reference and Change bit updates, while neither a context synchronizing operation nor the instruction fetching mechanism does so.

5. For data accesses, the context synchronizing instruction before the `tlbi, tlbiel, or tlbia` instruction ensures that all preceding instructions that access data storage have completed to a point at which they have reported all exceptions they will cause.

   The context synchronizing instruction after the `tlbi, tlbiel, or tlbia` instruction ensures that storage accesses associated with instructions following the context synchronizing instruction will not use the TLB entry(s) being invalidated.

   (If it is necessary to order storage accesses associated with preceding instructions, or Reference and Change bit updates associated with preceding address translations, with respect to subsequent data accesses, a `ptesync` instruction must also be used, either before or after the `tlbi, tlbiel, or tlbia` instruction. These effects of the `ptesync` instruction are described in the last paragraph of Note 8.)

6. The notation "([ptesync,CSI])" denotes an instruction sequence. Other instructions may be inter-leaved with this sequence, but these instructions must appear in the order shown.

   No software synchronization is required before the `Store` instruction because (a) stores are not performed out-of-order and (b) address translations associated with instructions preceding the `Store` instruction are not performed again after the store has been performed (see Section 5.5). These properties ensure that all address translations associated with instructions preceding the `Store` instruction will be performed using the old contents of the PTE.

   The `ptesync` instruction after the `Store` instruction ensures that all searches of the Page Table that are performed after the `ptesync` instruction completes will use the value stored (or a value stored subsequently). The context synchronizing instruction after the `ptesync` instruction ensures that any address translations associated with instructions following the context synchronizing instruction that were performed using the old contents of the PTE will be discarded, with the result that these address translations will be performed again and, if there is no corresponding entry in any implementation-specific address translation lookaside information, will use the value stored (or a value stored subsequently).

   The `ptesync` instruction also ensures that all storage accesses associated with instructions preceding the `ptesync` instruction, and all Reference and Change bit updates associated with additional address translations that were performed, by the thread executing the `ptesync` instruction, before the `ptesync` instruction is executed, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required attributes, before any data accesses caused by instructions following the `ptesync` instruction.
**sync** instruction are performed with respect to that thread or mechanism.

7. There are additional software synchronization requirements for this instruction in multi-threaded environments (e.g., it may be necessary to invalidate one or more TLB entries on all threads in the system and to be able to determine that the invalidations have completed and that all side effects of the invalidations have taken effect.

Section 5.10 gives examples of using **tlbie**, **Store**, and related instructions to maintain the Page Table, in both multi-threaded environments and environments consisting of only a single-threaded processor.

---

### Programming Note

In a multi-threaded system, if software locking is used to help ensure that the requirements described in Section 5.10 are satisfied, the **lwsync** instruction near the end of the lock acquisition sequence (see Section B.2.1.1 of Book II) may naturally provide the context synchronization that is required before the alteration.

8. The alteration must not cause an implicit branch in effective address space. Thus, when changing MSR_SF from 1 to 0, the **mtmsrd** instruction must have an effective address that is less than $2^{32} - 4$. Furthermore, when changing MSR_SF from 0 to 1, the **mtmsrd** instruction must not be at effective address $2^{32} - 4$ (see Section 5.3.2 on page 889).

9. The alteration must not cause an implicit branch in real address space. Thus the real address of the context-altering instruction and of each subsequent instruction, up to and including the next context synchronizing instruction, must be independent of whether the alteration has taken effect.

---

### Programming Note

If it is desired to set MSR_IR to 1 early in an operating system interrupt handler, advantage can sometimes be taken of the fact that EA03 are ignored when forming the real address when address translation is disabled and MSR_RV = 0. For example, if address translation resources are set such that effective address 0x000_0000_0000_0000 maps to real address 0x000_0000_0000_0000 when address translation is enabled, where n is an arbitrary 4-bit value, the following code sequence, in real page 0, can be used early in the interrupt handler.

```
la rx, target
li ry, 0x0n000
sldiry, ry, 48
or rx, rx, ry # set high-order nibble of target
               addr to 0xn
mtctrrx
bcctr  # branch to target
```

targ: mfsmsrrx
orirx, rx, 0x0020
mtmsrdrx # set MSR[IR] to 1

The **mtmsrd** does not cause an implicit branch in real address space because the real address of the next sequential instruction is independent of MSR_IR. Using **mtmsrd**, rather than **rtid** (or similar context synchronizing instruction that alters the control flow), may yield better performance on some implementations.

(Variations on the technique are possible. For example, the target instruction of the **bcctr** can be in arbitrary real page P, where P is a 48-bit value, provided that effective address 0xn || P || 0x000 maps to real address P || 0x000 when address translation is enabled.)

10. The elapsed time between the contents of the Decrementer or Hypervisor Decrementer becoming negative and the signaling of the corresponding exception is not defined.

11. If an **slbamte** instruction alters the mapping, or associated attributes, of a currently mapped ESID, the **slbamte** must be preceded by an **slbie** (or **slbia**) instruction that invalidates the existing translation. This applies even if the corresponding entry is no longer in the SLB (the translation may still be in implementation-specific address translation lookaside information). No software synchronization is needed between the **slbie** and the **slbamte**, regardless of whether the index of the SLB entry (if any) containing the current translation is the same as the SLB index specified by the **slbamte**.

No **slbie** (or **slbia**) is needed if the **slbamte** instruction replaces a valid SLB entry with a mapping of a
11. different ESID (e.g., to satisfy an SLB miss). However, the \textit{slbia} is needed later if and when the translation that was contained in the replaced SLB entry is to be invalidated.

12. The context synchronizing instruction before the \textit{mtspr} instruction ensures that the LPIDR is not altered out-of-order. (Out-of-order alteration of the LPIDR could permit the requirements described in Section 5.10.1 to be violated. For the same reason, such a context synchronizing instruction may be needed even if the new LPID value is equal to the old LPID value.)

See also Chapter 2. “Logical Partitioning (LPAR) and Thread Control” on page 843 regarding moving a thread from one partition to another.

13. When the RMOR or HRMOR is modified, or the VC, VRMASD, or RMLS fields of the LPCR are modified, software must invalidate all implementation-specific lookaside information used in address translation that depends on the old contents of these registers or fields (i.e., the contents immediately before the modification). The \textit{slbia} instruction can be used to invalidate all such implementation-specific lookaside information.

14. A context synchronizing instruction or event that is executed or occurs when LPCR\textsubscript{MER} = 1 does not necessarily ensure that the exception effects of LPCR\textsubscript{MER} are consistent with the contents of LPCR\textsubscript{MER}. See Section 2.2.

15. This line applies regardless of which SPR number (13 or 29) is used for the AMR.

16. LPIDR must not be altered when MSR\textsubscript{DR}=1 or MSR\textsubscript{IR}=1; if it is, the results are undefined.

17. This line applies to the following Performance Monitor SPRs: PMC1-6, MMCR0, MMCR1, MMCR2, and MMCRA.

18. This line applies to all SPR numbers that access the BESCR (800-803, 806).

19. There are additional software synchronization requirements when an \textit{mtspr} instruction modifies this SPR in a multi-threaded environment. See Section 2.8.

20. As an alternative to a CSI, the execution of an \textit{rfebb} instruction or the occurrence of an event-based branch is sufficient to provide the necessary synchronization.

21. These instructions and events, with the exception of nested \texttt{tbegin} and \texttt{tend}, TM instructions that except or are described to be treated as noops, \textit{Conditional Abort} instructions that do not abort, and events and \textit{rfebb} instructions for which the event did not take place in Transactional state, will change MSR\textsubscript{TS}. No explicit synchronization is required.
Appendix A. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided for certain instructions. This appendix defines extended mnemonics and symbols related to instructions defined in Book III. Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

A.1 Move To/From Special Purpose Register Mnemonics

This section defines extended mnemonics for the `mtspr` and `mfspr` instructions, including the Special Purpose Registers (SPRs) defined in Book I and certain privileged SPRs, and for the Move From Time Base instruction defined in Book II.

The `mtspr` and `mfspr` instructions specify an SPR as a numeric operand; extended mnemonics are provided that represent the SPR in the mnemonic rather than requiring it to be coded as an operand. Similar extended mnemonics are provided for the Move From Time Base instruction, which specifies the portion of the Time Base as a numeric operand.

**Note:** `mftb` serves as both a basic and an extended mnemonic. The Assembler will recognize an `mftb` mnemonic with two operands as the basic form, and an `mftb` mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).

---

**Programming Note**

The extended mnemonics in Table 6 for SPRs associated with the Performance Monitor facility are based on the definitions in Chapter 9.

Other versions of Performance Monitor facilities used different sets of SPR numbers (all 32-bit PowerPC implementations used a different set, and some early Power ISA implementations used yet a different set).

\(^1\) The \textit{mftb} instruction is Category: Phased-Out. Assemblers targeting Version 2.03 or later of the architecture should generate an \textit{mfspr} instruction for the mftb and mftbu extended mnemonics; see the corresponding Assembler Note in the \textit{mftb} instruction description (see Section 6.2.1 of Book II).
Appendix B. Interpretation of the DSISR as Set by an Alignment Interrupt

For most causes of Alignment interrupt, the interrupt handler will emulate the interrupting instruction. To do this, it needs the following characteristics of the interrupting instruction:

- Load or store
- Length (halfword, word, doubleword)
- String, multiple, or elementary
- Fixed-point or floating-point
- Update or non-update
- Byte reverse or not
- Is it dcbz?

The Power ISA optionally provides this information by setting bits in the DSISR that identify the interrupting instruction type. It is not necessary for the interrupt handler to load the interrupting instruction from storage. The mapping is unique except for a few exceptions that are discussed below. The near-uniqueness depends on the fact that many instructions, such as the fixed- and floating-point arithmetic instructions and the one-byte loads and stores, cannot cause an Alignment interrupt.

See Section 6.5.8 for a description of how the opcode and extended opcode are mapped to a DSISR value for an X-, D-, or DS-form instruction that causes an Alignment interrupt.

The table on the next page shows the inverse mapping: how the DSISR bits identify the interrupting instruction. The following notes are cited in the table.

1. For cases in which multiple instructions can give the same value for the DSISR bits (44:45 47:53) that are derived from the opcode, the Alignment interrupt handler should load the instruction from storage, using the effective address in SRR0, and treat the instruction appropriately (e.g., emulate the instruction, treat the case as a programming error, etc.). For example, if lbarx or lwarx causes an Alignment interrupt, it should not be emulated, but instead should be treated as a programming error.

2. These are distinguished by DSISR bits 44:45, which are not shown in the table.

The interrupt handler has no need to distinguish between an X-form instruction and the corresponding D- or DS-form instruction if one exists, and vice versa. Therefore two such instructions may yield the same DSISR value (all 32 bits). For example, stw and stwx may both yield either the DSISR value shown in the following table for stw, or that shown for stwx.
Power ISA™ - Book III-S
If DSISR 47:53 is:

then it is either X-form opcode:

or D/DS/DQ/DQE-form opcode:

so the instruction is:
Book III-E:

Power ISA Operating Environment Architecture - Embedded Environment [Category: Embedded]
Chapter 1. Introduction

1.1 Overview

Chapter 1 of Book I describes computation modes, document conventions, a general systems overview, instruction formats, and storage addressing. This chapter augments that description as necessary for the Power ISA Operating Environment Architecture.

1.2 32-Bit Implementations

Though the specifications in this document assume a 64-bit implementation, 32-bit implementations are permitted as described in Appendix C, “Guidelines for 64-bit Implementations in 32-bit Mode and 32-bit Implementations” on page 1249.

1.3 Document Conventions

The notation and terminology used in Book I apply to this Book also, with the following substitutions.

- For “system alignment error handler” substitute “Alignment interrupt”.
- For “system auxiliary processor enabled exception error handler” substitute “Auxiliary Processor Enabled Exception type Program interrupt”.
- For “system data storage error handler” substitute “Data Storage interrupt” or Data TLB Error interrupt as appropriate.
- For “system error handler” substitute “interrupt”.
- For “system floating-point enabled exception error handler” substitute “Floating-Point Enabled Exception type Program interrupt”.
- For “system illegal instruction error handler” substitute “Illegal Instruction exception type Program interrupt” or “Unimplemented Operation exception type Program interrupt”, as appropriate.
- For “system instruction storage error handler” substitute “Instruction Storage interrupt” or “Instruction TLB Error”, as appropriate.
- For “system privileged instruction error handler” substitute “Privileged Instruction exception type Program interrupt”.
- For “system service program” substitute “System Call interrupt”.
- For “system trap handler” substitute “Trap type Program interrupt”.

1.3.1 Definitions and Notation

The definitions and notation given in Books I and II are augmented by the following.

- Threaded processor, single-threaded processor, thread

A threaded processor implements one or more “threads”, where a thread corresponds to the Book I/II concept of “processor”. That is, the definition of “thread” is the same as the Book I definition of “processor”, and “processor” as used in Books I and II can be thought of as either a single-threaded processor or as one thread of a multi-threaded processor. The only unqualified uses of “processor” in Book III are in resource names (e.g. Processor Identification Register); such uses should be regarded as meaning “threaded processor”. The threads of a multi-threaded processor typically share certain resources, such as the hardware components that execute certain kinds of instructions (e.g., Fixed-Point instructions), certain caches, the address translation mechanism, and certain hypervisor resources.

- Thread enabled, thread disabled

A thread can be enabled or disabled. When enabled, the thread can prefetch and execute instructions; when disabled, prefetched instructions are discarded, and the thread cannot prefetch or execute instructions.

- Performed

An explicit modification, by a thread T1, of a shared SPR (using mtsp) or an entry in a shared TLB (using tlbwe), is performed with respect to thread T2 when a read of the shared SPR or TLB
entry (using `mfspr` or `tlbre` respectively) by T2 will return the result of the modification (or of a subsequent modification). For T2, the effects of such a modification having been performed with respect to T2 are the same as if the `mfspr` or `tlbre` were in T2’s instruction stream at the point at which the modification was performed with respect to T2. T1 and T2 may be any threads that share the SPR or TLB with one another, and may be the same thread.

- real page

A unit of real storage that is aligned at a boundary that is a multiple of its size. The real page size may range from 1KB to 1TB [MAV=1.0] or to 2TB [MAV=2.0].

- [MAV=x.x]

Instructions and facilities are considered part of all MMU architecture versions unless otherwise marked. If a facility or section is marked with a specific MMU Architecture version x.x, that facility or all material in that section and its subsections are considered part of the specific MMU architecture version.

- "must"

If the Embedded.Hypervisor category is not supported and privileged software violates a rule that is stated using the word “must”, the results are undefined. If the Embedded.Hypervisor category is supported, the following applies.

- If hypervisor software violates a rule that is stated using the word “must” (e.g., “this field must be set to 0”), and the rule pertains to the contents of a hypervisor resource, to executing an instruction that can be executed only in hypervisor state, or to accessing storage using a TLB entry with a TGS value of 0, the results are undefined, and may include altering resources belonging to other partitions, causing the system to “hang”, etc.

- If supervisor software violates the requirements for storage control bit values or their alteration, the result of accessing the associated storage is undefined.

- In other cases of violation of a rule that is stated using the word “must”, the results are boundedly undefined unless otherwise stated.

---

**Programming Note**

Contrary to the general principle of partition isolation, the result of accessing storage associated with violations of the requirements for storage control bit values and their alteration is specified as “undefined”. This is the only case where a guest operating system can cause “undefined” results. Embedded architecture does this as a hardware simplification because of the limited amount of code involved with storage control bits and because operating systems used in the Embedded environment can be tested and then controlled.

- context of a program

The state (e.g., privilege and relocation) in which the program executes. The context is controlled by the contents of certain System Registers, such as the MSR, of certain lookaside buffers, such as the TLB, and of other resources.

- exception

An error, unusual condition, or external signal, that may set a status bit and may or may not cause an interrupt, depending upon whether the corresponding interrupt is enabled.

- interrupt

The act of changing the machine state in response to an exception, as described in Chapter 7. “Interrupts and Exceptions” on page 1145.

- trap interrupt

An interrupt that results from execution of a `Trap` instruction.

- Additional exceptions to the sequential execution model, beyond those described in the section entitled “Instruction Fetching” in Book I, are the following.
  - A reset or Machine Check interrupt may occur. The determination of whether an instruction is required by the sequential execution model is not affected by the potential occurrence of a reset or Machine Check interrupt. (The determination is affected by the potential occurrence of any other kind of interrupt.)
  - A context-altering instruction is executed (Chapter 12. “Synchronization Requirements for Context Alterations” on page 1235). The context alteration need not take effect until the required subsequent synchronizing operation has occurred.
Any combination of hard-wired implementation, emulation assist, or interrupt for software assistance. In the last case, the interrupt may be to an architected location or to an implementation-dependent location. Any use of emulation assists or interrupts to implement the architecture is implementation-dependent.

- hypervisor privileged (or hypervisor-privileged)

If category E.HV is implemented, this term describes an instruction, register, or facility that is available only when the thread is in hypervisor state. Otherwise, this term describes an instruction, register, or facility that is available only when the thread is in supervisor state.

- privileged state and supervisor state

Used interchangeably to refer to a state in which privileged facilities are available.

- guest state

A state used to run software under control of a hypervisor program in which hypervisor-privileged facilities are not available.

- guest supervisor state

A state which is in both the guest state and the supervisor state.

- problem state and user mode

Used interchangeably to refer to a state in which privileged facilities are not available.

- volatile

Bits in a register or array (e.g., TLB) are considered volatile if they may change even if not explicitly modified by software.

- directed

In a hypervisor system, the attribute of an interrupt that execution occurs in the guest supervisor or hypervisor state as described in Section 2.3.1, “Directed Interrupts”.

- \(/, //, ///, ...\) denotes a field that is reserved in an instruction, in a register, or in an architected storage table.

- \(??, ??, ???, ...\) denotes a field that is implementation-dependent in an instruction, in a register, or in an architected storage table.

### 1.3.2 Reserved Fields

Some fields of certain architected registers may be written to automatically by the hardware, e.g., Reserved bits in System Registers. When the hardware writes to such a register, the following rules are obeyed.

- Unless otherwise stated, no defined field other than the one(s) specifically being updated are modified.

- Contents of reserved fields are either preserved or written as zero.

The reader should be aware that reading and writing of some of these registers (e.g., the MSR) can occur as a side effect of processing an interrupt and of returning from an interrupt, as well as when requested explicitly by the appropriate instruction (e.g., mtmsr instruction).

### 1.4 General Systems Overview

The hardware contains the sequencing and processing controls for instruction fetch, instruction execution, and interrupt action. Most implementations also contain data and instruction caches. Instructions fall into the following classes:

- instructions executed in the Branch Facility
- instructions executed in the Fixed-Point Facility
- instructions executed in the Floating-Point Facility
- instructions executed in the Vector Facility
- instructions executed in an Auxiliary Processor
- other instructions

Almost all instructions executed in the Branch Facility, Fixed-Point Facility, Floating-Point Facility, and Vector Facility are nonprivileged and are described in Book I. Book I may describe additional nonprivileged instructions (e.g., Book II describes some nonprivileged instructions for cache management). Instructions executed in an Auxiliary Processor are implementation-dependent. Instructions related to the supervisor mode, control of hardware resources, control of the storage hierarchy, and all other privileged instructions are described here or are implementation-dependent.

### 1.5 Exceptions

The following augments the exceptions defined in Book I that can be caused directly by the execution of an instruction:

- the execution of a floating-point instruction when MSR<sub>FP</sub>=0 (Floating-Point Unavailable interrupt)
- execution of an instruction that causes a debug event (Debug interrupt).
- the execution of an auxiliary processor instruction when the auxiliary processor is unavailable (Auxiliary Processor Unavailable interrupt)
- the execution of a Vector, SPE, or Embedded Floating-Point instruction when MSR<sub>SPV</sub>=0 (SPE/Embedded Floating-Point/Vector Unavailable interrupt)
1.6 Synchronization

The synchronization described in this section refers to the state of the thread that is performing the synchronization.

1.6.1 Context Synchronization

An instruction or event is context synchronizing if it satisfies the requirements listed below. Such instructions and events are collectively called context synchronizing operations. The context synchronizing operations include the dh instruction, the isync instruction, the System Linkage instructions, and most interrupts (see Section 7.1). Also, the combination of disabling and enabling a thread is context-synchronizing for the thread being enabled (See Section 3).

1. The operation causes instruction dispatching (the issuance of instructions by the instruction fetching mechanism to any instruction execution mechanism) to be halted.

2. The operation is not initiated or, in the case of dh, isync does not complete, until all instructions that precede the operation have completed to a point at which they have reported all exceptions they will cause.

3. The operation ensures that the instructions that precede the operation will complete execution in the context (privilege, relocation, storage protection, etc.) in which they were initiated.

4. If the operation directly causes an interrupt (e.g., sc directly causes a System Call interrupt) or is an interrupt, the operation is not initiated until no exception exists having higher priority than the exception associated with the interrupt (see Section 7.9, “Exception Priorities” on page 1190).

5. The operation ensures that the instructions that follow the operation will be fetched and executed in the context established by the operation. (This requirement dictates that any prefetched instructions be discarded and that any effects and side effects of executing them out-of-order also be discarded, except as described in Section 6.5, “Performing Operations Out-of-Order”.)

The operation ensures that all explicit modifications of shared SPRs (mtspr) and shared TLBs (tlbwe), caused by instructions that precede the operation, have been performed with respect to all other threads that share the SPR or TLB.

---

**Programming Note**

The context established by a context synchronizing instruction includes modifications to certain resources that were performed with respect to the context synchronizing thread before the operation was initiated. The resources in this case include shared SPRs that contain program context such as LPIDR as well as TLBs shared by other threads.

---

**Programming Note**

A context synchronizing operation is necessarily execution synchronizing; see Section 1.6.2.

Unlike the Synchronize instruction, a context synchronizing operation does not affect the order in which storage accesses are performed.

Item 2 permits a choice only for isync (and sync; see Section 1.6.2) because all other execution synchronizing operations also alter context.

1.6.2 Execution Synchronization

An instruction is execution synchronizing if it satisfies items 2 and 3 of the definition of context synchronization (see Section 1.6.1). sync is treated like isync with respect to item 2. The execution synchronizing instructions are sync, mtmsr and all context synchronizing instructions.

---

**Programming Note**

Unlike a context synchronizing operation, an execution synchronizing instruction does not ensure that the instructions following that instruction will execute in the context established by that instruction. This new context becomes effective sometime after the execution synchronizing instruction completes and before or at a subsequent context synchronizing operation.
Chapter 2. Logical Partitioning [Category: Embedded.Hypervisor]

2.1 Overview

The Embedded.Hypervisor category permits threads and portions of real storage to be assigned to logical collections called partitions, such that a program executing in one partition cannot interfere with any program executing in a different partition. This isolation can be provided for both problem state and privileged state programs, by using a layer of trusted software, called a hypervisor program (or simply a “hypervisor”), and the resources provided by this facility to manage system resources. The collection of software that runs in a given partition and its associated resources is called a guest. The guest normally includes an operating system (or other system software) running in privileged state and its associated processes running in the problem state under the management of the hypervisor. The thread is in the guest state when a guest is executing and is in the hypervisor state when the hypervisor is executing. The thread is executing in the guest state when MSRGS=1.

The number of partitions supported is implementation-dependent.

A thread is assigned to one partition at any given time. A thread can be assigned to any given partition without consideration of the physical configuration of the system (e.g. shared registers, caches, organization of the storage hierarchy), except that threads that share certain hypervisor resources may need to be assigned to the same partition. Additionally, certain resources may be utilized by the guest at the discretion of the hypervisor. Such usage may cause interference between partitions and the hypervisor should allocate those resources accordingly. The primary registers and facilities used to control Logical Partitioning are listed below and described in the following subsections. Other facilities associated with Logical Partitioning are described within the appropriate sections within this Book.

An instruction that is hypervisor privileged must be execute in the hypervisor state (MSRGS PR = 0b00). If an attempt is made to execute a hypervisor-privileged instruction in the guest supervisor state (MSRGS PR = 0b10), an Embedded Hypervisor Privilege exception occurs. A register that is hypervisor privileged may only be accessed in the hypervisor state (MSRGS PR = 0b00). If a hypervisor-privileged register is accessed in the guest supervisor state (MSRGS PR = 0b10), an Embedded Hypervisor Privilege exception occurs.

When MSRGS PR = 0b01 or MSRGS PR = 0b11, the thread is in problem (user) state. The resources (instructions and registers) that are available are generally the same when MSRP R = 0b1 regardless of the state of MSRGS; however when MSRGS PR = 0b11 some interrupts are directed to the guest supervisor state. When MSRGS PR = 0b01 interrupts are always directed to the hypervisor (see Section 2.3.1, “Directed Interrupts”).

Category Embedded.Hypervisor changes the operating system programming model to allow for easier virtualization, while retaining a default backward compatible mode in which an operating system written for hardware not implementing this category will still operate as before without using the Logical Partitioning facilities.

Category Embedded.Hypervisor requires that Category: Embedded.Processor Control is also supported.

2.2 Registers

Registers specific to Logical Partitioning and hypervisor control are defined in this section. Other registers which are hypervisor privileged or have hypervisor-only fields appear and are described in other sections in this Book.

2.2.1 Register Mapping

To facilitate better performance for operating systems executing in the guest supervisor state, some Special Purpose Register (SPR) accesses are redirected to analogous guest-state SPRs. An SPR is said to be mapped if this redirection takes place when executing in guest supervisor state. These guest-state SPRs separate performance critical state of the hypervisor and the operating system executing in guest supervisor state.
state. The mapping of these register accesses allows the same programming model to be used for an operating system running in the guest supervisor state or in the hypervisor state.

For example, when a $\text{mtspr}\ SRR0,r5$ instruction is executed in guest supervisor state, the access to SRR0 is mapped to GSRR0. This produces the same operation as executing $\text{mtspr}\ GSRR0,r5$.

---

**Programming Note**

Since accesses to the mapped SPRs are automatically mapped to the appropriate guest-accessible SPR, guest supervisor software should use the original SPRs for accessing these registers (i.e. SRR0, not GSRR0). This facilitates using the same code in hypervisor or guest state.

SPR accesses that are mapped in guest supervisor state are listed in Table 1.

<table>
<thead>
<tr>

</tbody>
</table>

1 If an implementation permits problem state read access to SPRG3, the problem state read access is remapped to GSPRG3.

Table 1: Mapped SPRs

---

### 2.2.2 Logical Partition Identification Register (LPIDR)

The Logical Partition Identification Register (LPIDR) contains the Logical Partition ID (LPID) currently in use for the thread. The format of the LPIDR is shown in Figure 1 below.

---

**2.3 Interrupts and Exceptions**

#### 2.3.1 Directed Interrupts

Category Embedded.Hypervisor introduces new interrupt semantics. Interrupts are directed to either the guest state or the hypervisor state. The state to which interrupts are directed determines which SPRs are used to form the vector address, which save/restore registers are used to capture the thread state at the time of the interrupt, and which registers are used to post exception status.

- If IVORs [Category: Embedded.Phased-Out] are supported, interrupts directed to the guest state use the Guest Interrupt Vector Prefix Register (GIVPR) to determine the high-order 48 bits of the vector address and use Guest Interrupt Vector Registers (GIVORs) to provide the low-order 16 bits (of which the last 4 bits are 0).
- If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, interrupts directed to the guest state use the Guest Interrupt Vector Prefix Register (GIVPR) to determine the high-order 52 bits of the vector address and use the 12-bit exception vector offsets (described in Section 7.2.15) to provide the low-order 12 bits (of which the last 5 bits are 0).
- If IVORs [Category: Embedded.Phased-Out] are supported, interrupts directed to the Embedded hypervisor state use the IVPR for the upper 48 bits of the address and the IVORs for the lower 16 bits of the address.
- If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, interrupts directed to the Embedded hypervisor state use one of the following for the interrupt vector address.
  - If the Machine Check Interrupt Vector Prefix Register (see Section 7.2.18.4) is supported and the interrupt is a Machine Check, MCIVPR provides the high-order 52 bits of the vector address and the 12-bit exception vector offsets (described in Section 7.2.15) provides the low-order 12 bits (of which the last 5 bits are 0).
  - Otherwise, IVPR provides the high-order 52 bits of the vector address and the 12-bit exception vector offsets (described in Section
7.2.15) provides the low-order 12 bits (of which the last 5 bits are 0).

Interrupts that are directed to the guest state use GSRR0/GSRR1 registers to save the context at interrupt time. Interrupts directed to the embedded hypervisor state use SRR0/SRR1, with the exception of Guest Processor Doorbell interrupts which use GSRR0/GSRR1.

All interrupts are directed to the hypervisor except when the processor is already in guest state (MSRGS = 1) and:
- The interrupt is a system call and the LEVEL field is 0.
- The interrupt is a Data TLB Error, Instruction TLB Error, Data Storage Interrupt, Instruction Storage Interrupt, or External Input Interrupt and the corresponding bit in the EPCR to direct these interrupts to guest state is a 1 and the interrupt is not caused by either a Virtualization Fault or a TLB Ineligible Exception.

### 2.3.2 Hypervisor Service Interrupts

Two interrupts exist as mechanisms for the hypervisor to provide services to the guest.

The Embedded Hypervisor Privilege Interrupt occurs when guest supervisor state attempts execution of a hypervisor-privileged instruction or attempts to access a hypervisor-privileged resource. This can be used by the hypervisor to provide virtualization services for the guest. The Embedded Hypervisor Privilege Interrupt is described in Section 7.6.31, “Embedded Hypervisor Privilege Interrupt [Category: Embedded.Hypervisor]”. An Embedded Hypervisor Privilege Interrupt will also occur if a `ehpriv` instruction is executed regardless of the thread state.

The Embedded Hypervisor System Call Interrupt occurs when an `sc` instruction is executed and LEV = 1. The `sc` instruction is described in Section 4.3.1, “System Linkage Instructions”.

### 2.4 Instruction Mapping

When executing in the guest supervisor state (MSRGS PR = 0b10), execution of an `rfi` instruction is mapped to `rfgi` and the `rfgi` instruction is executed in place of the `rfi`. The mapping of these instructions allows the same programming model to be used for an operating system running in the guest supervisor state or in the hypervisor state.
Chapter 3. Thread Control [Category: Embedded Multi-Threading]

3.1 Overview

The Thread Control facility permits the hypervisor to control and monitor the execution, priority, and other aspects of threads.

3.2 Thread Identification Register (TIR)

The layout of the TIR is shown in below.

Figure 2. Thread Identification Register

The TIR is a 64-bit read-only register that can be used to distinguish the thread from other threads on a multi-threaded processor. Threads are numbered sequentially, with valid values ranging from 0 to t-1, where t is the number of threads implemented. A thread for which $TIR = n$ is referred to as “thread n.”

The TIR is hypervisor privileged.

3.3 Thread Enable Register (TEN)

The layout of the TEN is shown in below.

Figure 3. Thread Enable Register

The TEN is a 64-bit register. For $t < T$, where $T$ is the number of threads supported by the implementation, bit 63-t corresponds to thread t. When $TEN_{63-t}$ is 0, thread t is disabled. When $TEN_{63-t}$ is 1, thread t is enabled.

Software is permitted to write any value to bits 0:63-T; a subsequent reading of these bits always returns 0.

The TEN can be accessed using two SPR numbers.

- When SPR 438 (Thread Enable Set, or TENS) is written, threads for which the corresponding bit in TENS is 1 are enabled; threads for which the corresponding bit in TENS is 0 are unaffected.

- When SPR 439 (Thread Enable Clear, or TENC) is written, threads for which the corresponding bit in TENC is 1 are disabled; threads for which the corresponding bit in TENC is 0 are unaffected.

When each SPR is read, the current value of the TEN is returned.

The TEN is hypervisor privileged.

3.4 Thread Enable Status Register (TENSR)

The layout of the TENSR is shown in below.

Figure 4. Thread Enable Status Register

32-bit implementations are limited to 32 threads. In 64-bit mode, the high order 32 bits of TEN are not modified when written. See Section 1.5.2, "Modes [Category: Embedded]", in Book I.

Software can determine the number of threads supported by the implementation by setting each progressively higher-order bit to 1, and testing whether a subsequent read returns a 1. Because this operation enables the thread, software should ensure that an acceptable instruction sequence is located at the thread's starting effective address. (See Section 8.3, "Thread State after Reset".)
The TENSR is a 64-bit read-only register. Bit 63-t of the TENSR corresponds to thread t. The contents of the TENSR are equal to the contents of the TEN, except that when TEN63-t changes from 1 to 0, TENSR63-t does not change from 1 to 0 until thread t is disabled.

The TENSR is hypervisor privileged.

Architectural Note

32-bit implementations are limited to 32 threads.

3.5 Disabling and Enabling Threads

The combination of disabling and enabling a thread is context-synchronizing for the thread being enabled. Steps 1-3 of context synchronization (see Section 1.6.1) occur as a result of the thread being disabled, and updates to SPRs and shared TLBs caused by preceding instructions executed by the thread occur. When all updates to these shared SPRs and shared TLBs have been performed with respect to all other threads on a multi-threaded processor, the TENSR bit corresponding to the disabled thread is set to 0.

Asynchronous interrupts that occur after the thread is disabled are pended until the thread is enabled.

When a thread is enabled by setting the TEN bit corresponding to the thread to 1, the thread begins execution at the next instruction to be executed when it was disabled or at the effective address specified by the INIA [Category: Embedded Multi-threading.Thread Management] if the INIA corresponding to the thread was written while the thread was disabled.

Programming Note

The architecture provides no method to make a thread's updates to shared storage visible to other threads before it is disabled. Similarly, the architecture provides no method to make updates to shared storage made while a thread is disabled visible to a thread when it is subsequently enabled.

Programming Note

When thread T1 disables other threads, Tn, it sets the TEN bits corresponding to Tn to 0s. In order to ensure that all updates to shared SPRs and shared TLBs caused by instructions being performed by threads Tn have been performed with respect to all threads on a multi-threaded processor, thread T1 reads the TENSR until all the bits corresponding to the disabled threads, Tn, are 0s.

3.6 Sharing of Multi-Threaded Processor Resources

The PVR and TEN must be shared among all threads of a multi-threaded processor. Various other resources are allowed to be shared among threads. Programs that modify shared resources must be aware of such sharing, and must allow for the fact that changes to these resources may affect more than one thread.

Resources that may be shared are grouped into the following five groups of related resources. If any of the resources in a group are shared among threads, all of the resources in the group must be shared.

- ATB, ATBL, ATBU [Category: ATB]
- IVORs [Category: Phased-Out]
- IVPR
- TB, TBL, TBU
- MMUCFG, MMUCSR0, TLB, TLBnCFG, TLBnCFG2, TLBnEPT, [Category: Embedded.Hypervisor.LRAT]: LRAT, LRATCFG, LRATCFG2

If the implementation requires all threads to be in the same partition, the following additional groups of resources may be shared. If any of the resources in a group are shared among threads, all of the resources in the group must be shared.

- DAC1, DAC2, IAC1, IAC2, IAC3
- EHCSR [Category: Embedded.Hypervisor]
- GIVORs [Category: Phased-Out]
- GIVPR [Category: Embedded.Hypervisor]
- LPIDR [Category: Embedded.Hypervisor]

Certain implementation-dependent registers, instruction and Data Caches, and implementation-dependent look-aside information may also be shared.

The set of resources that is shared is implementation-dependent.
When software executing in thread T1 writes a new value in an SPR (mtspr) that is shared with other threads, or explicitly writes to an entry in a shared TLB (tlbwe), either of the following sequences of operations can be performed in order to ensure that the write operation has been performed with respect to other threads.

Sequence 1

- Disable all other threads (see Section 3.5)
- Write to the shared SPR (mtspr) or to the shared TLB (tlbwe)
- Perform a context synchronizing operation
- Enable the previously-disabled threads

In the above sequence, the context synchronizing operation ensures that the write operation has been performed with respect to all other threads that share the SPR or TLB; the enabling of other threads ensures that subsequent instructions of the enabled threads use the new SPR or TLB value since enabling a thread is a context synchronizing operation.

Sequence 2

- All threads are put in hypervisor state and begin polling a storage flag
- The thread updating the SPR or TLB does the following:
  - Writes to the SPR (mtspr) or the TLB (tlbwe)
  - Sets a storage flag indicating the write operation was done
  - Performs a context synchronizing operation
- When other threads see the updated storage flag, they perform context synchronizing operations.

In the above sequence, the context synchronizing operation by the thread that writes to the SPR or TLB ensures that the write operation has been performed with respect to all other threads that share the SPR or TLB; the context synchronizing operation by the other threads ensure that subsequent instructions for these threads use the updated value.

### Programming Note

When software executing in thread T1 writes a new value in an SPR (mtspr) that is shared with other threads, or explicitly writes to an entry in a shared TLB (tlbwe), either of the following sequences of operations can be performed in order to ensure that the write operation has been performed with respect to other threads.

Sequence 1

- Disable all other threads (see Section 3.5)
- Write to the shared SPR (mtspr) or to the shared TLB (tlbwe)
- Perform a context synchronizing operation
- Enable the previously-disabled threads

In the above sequence, the context synchronizing operation ensures that the write operation has been performed with respect to all other threads that share the SPR or TLB; the enabling of other threads ensures that subsequent instructions of the enabled threads use the new SPR or TLB value since enabling a thread is a context synchronizing operation.

Sequence 2

- All threads are put in hypervisor state and begin polling a storage flag
- The thread updating the SPR or TLB does the following:
  - Writes to the SPR (mtspr) or the TLB (tlbwe)
  - Sets a storage flag indicating the write operation was done
  - Performs a context synchronizing operation
- When other threads see the updated storage flag, they perform context synchronizing operations.

In the above sequence, the context synchronizing operation by the thread that writes to the SPR or TLB ensures that the write operation has been performed with respect to all other threads that share the SPR or TLB; the context synchronizing operation by the other threads ensure that subsequent instructions for these threads use the updated value.

### Figure 5. Initialize Next Instruction Address Register

### 3.7 Thread Management Facility

[Category: Embedded Multi-threading.Thread Management]

The thread management facility enables software to control features related to threads. The capabilities provided allow software, for a disabled thread, to specify the address of the instruction to be executed when the thread is enabled. Other implementation-dependent capabilities may also be provided.

#### 3.7.1 Initialize Next Instruction Address Registers

The Initialize Next Instruction Address (INIAn, where n = 0..63) registers are 64-bit write-only registers that can be used to specify the effective address of the instruction to be executed when a currently-disabled thread is enabled. INIAn corresponds to thread n.

The initial value of all INIAs is $0xFFFF_FFFF_FFFF_FFFC$.
3.7.2 Thread Management Instructions

Move To Thread Management Register

\textit{XFX-form}

\texttt{mttmr} \text{ TMR,RS}

\begin{center}
\begin{tabular}{|c|c|c|c|c|}
\hline
0 & 31 & 6 & 494 & / 11 & 21 & 31 \\
\hline
\end{tabular}
\end{center}

\( n \leftarrow \text{tmr}_{5:9} || \text{tmr}_{0:4} \)

\( \text{TMR}(n) \leftarrow (\text{RS}) \)

The TMR field denotes a Thread Management Register, encoded as shown in the table below. The contents of register RS are placed into the designated Thread Management Register.

\begin{center}
\begin{tabular}{|c|c|c|}
\hline
\textbf{decimal} & \textbf{TMR} & \textbf{Register Name} \\
\hline
320 & 01010 00000 & \text{INIA}_0 \\
\hline
\ldots & \ldots & \ldots \\
383 & 10111 11111 & \text{INIA}_{63} \\
\hline
\end{tabular}

\textsuperscript{1} Note that the order of the two 5-bit halves of the SPR number is reversed.
\end{center}

Figure 6. Thread Management Register Numbers

All values of the TMR field not shown in Figure 6 are implementation-specific.

An implementation only provides INIA registers corresponding to its implemented threads. Execution of this instruction specifying a TMR number that is not defined for the implementation causes an Illegal Instruction type Program interrupt if MSR\_GS\_PR=0b00.

This instruction is hypervisor privileged.

\textbf{Special Registers Altered:} \\
See above
4.1 Branch Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Branch Facility that are not covered in Book I.

4.2 Branch Facility Registers

4.2.1 Machine State Register

The MSR (MSR) is a 32-bit register. MSR bits are numbered 32 (most-significant bit) to 63 (least-significant bit). This register defines the state of the thread. The MSR can also be modified by the \textit{mtmsr}, \textit{rfi}, \textit{rfci}, \textit{rfdi} [Category: Embedded.Enhanced Debug], \textit{rfmci}, \textit{rfgi} [Category: Embedded.Hypervisor], \textit{wrtee} and \textit{wrteei} instructions and interrupts. It can be read by the \textit{mfmsr} instruction.

![Machine State Register](image)

Below are shown the bit definitions for the Machine State Register.

<table>
<thead>

Virtualized Implementation Note

In a virtualized implementation, MSR$_{GS}$ will be 1.

Implementation-dependent

\textbf{User Cache Locking Enable} (UCLE) [Category: Embedded Cache Locking,User Mode]

0 \textit{Cache Locking} instructions are privileged.
1 \textit{Cache Locking} instructions can be executed in user mode (MSR$_{PR}$=1).

If Category: Embedded Cache Locking,User Mode is not supported, this bit is treated as reserved.

\textbf{SP/Embedded Floating-Point/Vector Available} (SPV) [Category: Signal Processing]:

0 The thread cannot execute any SP instructions except for the \textit{brinc} instruction.
1 The thread can execute all SP instructions.

[Category: Vector]:

0 The thread cannot execute any Vector instruction.
1 The thread can execute Vector instructions.

Reserved
40  **VSX Available** (VSX)

0  The thread cannot execute any VSX instructions, including VSX loads, stores, and moves.
1  The thread can execute VSX instructions.

---

**Programming Note**

An application binary interface defined to support Category: Vector-Scalar operations should also specify a requirement that MSR. FP and MSR. VEC be set to 1 whenever MSR. VSX is set to 1.

41:45  Reserved

46  **Critical Enable** (CE)

0  Critical Input, Watchdog Timer, Guest Processor Doorbell Critical <E.HV>, and Processor Doorbell Critical interrupts are disabled.
1  Critical Input, Watchdog Timer, Guest Processor Doorbell Critical <E.HV>, and Processor Doorbell Critical interrupts are enabled.

---

[Category: Embedded.Hypervisor]

Critical level interrupts with the exception of Guest Processor Doorbell Critical are enabled regardless of the state of MSR CE when MSR GS = 1.

47  Reserved

48  **External Enable** (EE)

0  External Input, Decrementer, Fixed-Interval Timer, Processor Doorbell, Guest Processor Doorbell <E.HV> and Embedded Performance Monitor <E.PM> interrupts are disabled.
1  External Input, Decrementer, Fixed-Interval Timer, Processor Doorbell, Guest Processor Doorbell <E.HV>, and Embedded Performance Monitor <E.PM> interrupts are enabled.

---

[Category: Embedded.Hypervisor]

When an interrupt that is maskable by MSR EE is directed to the hypervisor state, the interrupt is enabled if MSR EE=1 or MSR GS=1 except for Guest Processor Doorbell which is enabled if MSR EE=1 and MSR GS=1. When an interrupt that is maskable by MSR EE is directed to the guest supervisor state, the interrupt is enabled if MSR EE=1 and MSR GS=1. Also, see the EXTGS bit in Section 4.2.3.

49  **Problem State** (PR)

0  The thread is in privileged state (supervisor state).
1  The thread is in problem state (user mode).

MSR PR also affects storage access control, as described in Section 6.7.6

50  **Floating-Point Available** (FP)

[Category: Floating-Point]

0  The thread cannot execute any floating-point instructions, including floating-point loads, stores and moves.
1  The thread can execute floating-point instructions.

---

51  **Machine Check Enable** (ME)

0  Machine Check interrupts are disabled.
1  Machine Check interrupts are enabled.

---

[Category: Embedded.Hypervisor]

Machine Check interrupts with the exception of Guest Processor Doorbell Machine Check are enabled regardless of the state of MSR ME when MSR GS = 1.

52  **Floating-Point Exception Mode 0** (FE0)

[Category: Floating-Point]

(See below)

53  Implementation-dependent

54  **Debug Interrupt Enable** (DE)

0  Debug interrupts are disabled.
1  Debug interrupts are enabled if DBCR0IDM=1

---

**Virtualized Implementation Note**

In a virtualized implementation, when MSR DE=1, the registers SPRG9, DSRR0, and DSRR1 are volatile.

55  **Floating-Point Exception Mode 1** (FE1)

[Category: Floating-Point]

(See below)

56  Reserved

57  Reserved

58  **Instruction Address Space** (IS)

0  The thread directs all instruction fetches to address space 0 (TS=0 in the relevant TLB entry).
1  The thread directs all instruction fetches to address space 1 (TS=1 in the relevant TLB entry).

---

59  **Data Address Space** (DS)
0 The thread directs all data storage accesses to address space 0 (TS=0 in the relevant TLB entry).
1 The thread directs all data storage accesses to address space 1 (TS=1 in the relevant TLB entry).

60 Implementation-dependent
61 Performance Monitor Mark (PMM) [Category: Embedded.Performance Monitor]
0 Disable statistics gathering on marked processes.
1 Enable statistics gathering on marked processes

See Appendix D for additional information.

62 Reserved
63 Reserved

The Floating-Point Exception Mode bits FE0 and FE1 are interpreted as shown below. For further details see Book I.

</tr>
</tbody>
</table>

See Section 8.3 for the initial state of the MSR.

[Category: Embedded.Hypervisor]
Some bits in the MSR can only be changed when the thread is in hypervisor state or the MSRP register has been configured to allow changes in the guest supervisor state. See Section 4.2.2, "Machine State Register Protect Register (MSRP)".

**Programming Note**
A Machine State Register bit that is reserved may be altered by rfi/rdi [Category: Embedded.Enhanced Debug]/rfi [Category: Embedded.Hypervisor].

4.2.2 Machine State Register Protect Register (MSRP)

The Machine State Register Protect Register (MSRP) controls whether certain bits in the Machine State Register (MSR) can be modified in guest supervisor state. In addition, the MSRP impacts the behavior of cache locking and performance monitor instructions in guest state, as described below. The format of the MSRP is shown in Figure 8 below.

![Figure 8. Machine State Register Protect Register](image)

The MSRP is used to prevent guest supervisor state program from modifying the UCLE, DE, or PMM bits in the MSR. The MSRP bits UCLEP, DEP, and PMMP control whether the guest can change the corresponding MSR bits UCLE, DE, and PMM, respectively. When the MSRP bit associated with a corresponding MSR bit is 0, any operation in guest privileged state is allowed to modify that MSR bit, whether from an instruction that modifies the MSR, or from an interrupt which is taken in the guest supervisor state. When the MSRP bit associated with a corresponding MSR bit is 1 no operation in guest privileged state is allowed to modify that MSR bit (i.e., it remains unchanged), whether from an instruction that modifies the MSR, or from an interrupt from the guest state which is taken in the guest supervisor state.

These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bit</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:36</td>
<td>Reserved</td>
</tr>
<tr>
<td>37</td>
<td>User Cache Lock Enable Protect (UCLEP) [Category: ECL]</td>
</tr>
<tr>
<td>0</td>
<td>MSR_{UCLE} can be modified in guest supervisor state.</td>
</tr>
<tr>
<td>1</td>
<td>MSR_{UCLE} cannot be modified in guest supervisor state and guest state cache locking using dcbtls, dcbtstls, dcblc, dcblq, icbtls, icblq, and icblc is affected as described later in this section.</td>
</tr>
<tr>
<td>38:53</td>
<td>Reserved</td>
</tr>
<tr>
<td>54</td>
<td>Debug Enable Protect (DEP)</td>
</tr>
<tr>
<td>0</td>
<td>MSR_{DE} can be modified in guest supervisor state.</td>
</tr>
<tr>
<td>1</td>
<td>MSR_{DE} cannot be modified in guest supervisor state.</td>
</tr>
<tr>
<td>55:60</td>
<td>Reserved</td>
</tr>
<tr>
<td>61</td>
<td>Performance Monitor Mark Protect (PMMP) [Category: E.PM]</td>
</tr>
<tr>
<td>0</td>
<td>MSR_{PMM} can be modified in guest supervisor state.</td>
</tr>
<tr>
<td>1</td>
<td>MSR_{PMM} cannot be modified in guest supervisor state and guest state accesses to Performance Monitor Registers using mfpmr and mtpmr are affected as described later in this section.</td>
</tr>
<tr>
<td>62:63</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The MSRP is hypervisor privileged.
A context synchronizing operation must be performed following a change to MSRP to ensure that its changes are visible in the current context.

The behavior of cache locking instructions (dcbtls, dcbltsl, dcblc, dcblq, icbtl, icblq, icblc) in guest privileged state is dependent on the setting of MSRP_UCLEP. When MSRP_UCLEP = 0, cache locking instructions are permitted to execute normally in the guest privileged state. When MSRP_UCLEP = 1, cache locking instructions are not permitted to execute in the guest privileged state and cause an Embedded Hypervisor Privilege exception. [Category: ECL]

The behavior of Performance Monitor instructions (mtprm, mfpmr) is dependent on the setting of MSRP_PMMMP. When MSRP_PMMMP = 0, Performance Monitor instructions are permitted to execute normally in the guest state. When MSRP_PMMMP = 1, Performance Monitor instructions are not permitted to execute normally in the guest state. Execution of a mfpmr instruction which specifies a user Performance Monitor register produces a value of 0 in the destination GPR. In the guest supervisor state (MSRP = 0 and MSR GS = 1), execution of any mfpmr instruction or execution of a mfpmr instruction which specifies a privileged Performance Monitor Register produces an Embedded Hypervisor Privilege exception. [Category: E.PM]

### Programming Note

Setting the MSRP to 0 at initialization allows guest state access to MSR UCLE, DE, PMMP and the associated cache locking and performance monitor facilities.

#### 4.2.3 Embedded Processor Control Register (EPCR)

The Embedded Processor Control Register (EPCR) provides general controls for both privileged and hypervisor privileged facilities. The format of the EPCR is shown in Figure 1 below.

**Figure 9. Embedded Processor Control Register**

These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bit</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>External Input Interrupt Directed to Guest State (EXTGS) [Category: Embedded.Hypervisor]</td>
</tr>
<tr>

</tr>
<tr>
<td>33</td>
<td>Data TLB Error Interrupt Directed to Guest State (DTLBGS) [Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Controls whether a Data TLB Error Interrupt that occurs in the guest state is taken in the guest supervisor state or the hypervisor state.</td>
</tr>
<tr>
<td>34</td>
<td>Instruction TLB Error Interrupt Directed to Guest State (ITLBGS) [Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Controls whether an Instruction TLB Error Interrupt that occurs in the guest state is taken in the guest supervisor state or the hypervisor state.</td>
</tr>
<tr>
<td>35</td>
<td>Data Storage Interrupt Directed to Guest State (DSIGS) [Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Controls whether a Data Storage Interrupt that occurs in the guest state is taken in the guest supervisor state or the hypervisor state, except for an interrupt caused by a TLB Ineligible exception &lt;E.PT&gt;.</td>
</tr>
<tr>
<td>36</td>
<td>Instruction Storage Interrupt Directed to Guest State (ISIGS) [Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Controls whether an Instruction Storage Interrupt that occurs in the guest state is taken in the guest supervisor state or the hypervisor state.</td>
</tr>
</tbody>
</table>
state, except for an interrupt caused by a TLB ineligible exception <E.PT>.

0 Instruction Storage Interrupts that occur in the guest supervisor state are directed to the hypervisor state.
1 Instruction Storage Interrupts that occur in the guest state are directed to the guest supervisor state.

37 **Disable Embedded Hypervisor Debug** (DUVD)
   [Category: Embedded.Hypervisor]
   Controls whether Debug Events occur in the hypervisor state.
   0 Debug events can occur in the hypervisor state.
   1 Debug events, except for the Unconditional Debug Event, are suppressed in the hypervisor state. It is implementation-dependent whether the Unconditional Debug Event is suppressed.

38 **Interrupt Computation Mode** (ICM)
   [Category: 64-bit]
   If category E.HV is implemented, this bit controls the computational mode of the thread when an interrupt occurs that is directed to the hypervisor state. At interrupt time, EPCR_{ICM} is copied into MSR_{CM} if the interrupt is directed to the hypervisor state.

   If category E.HV is not implemented, then this bit controls the computational mode of the thread when any interrupt occurs. At interrupt time, EPCR_{ICM} is copied into MSR_{CM}.
   0 Interrupts will execute in 32-bit mode.
   1 Interrupts will execute in 64-bit mode.

39 **Guest Interrupt Computation Mode** (GICM)
   [Category: Embedded.Hypervisor]
   [Corequisite Category: 64-bit]
   Controls the computational mode of the thread when an interrupt occurs that is directed to the guest supervisor state. At interrupt time, EPCR_{GICM} is copied into MSR_{CM} if the interrupt is directed to the guest supervisor state.
   0 Interrupts will execute in 32-bit mode.
   1 Interrupts will execute in 64-bit mode.

40 **Disable Guest TLB Management Instructions** (DGTMI)
   [Category: Embedded.Hypervisor]
   Controls whether guest supervisor state can execute any TLB management instructions.
   0 **tlbsr** and **tlbwe** (for a Logical to Real Address translation hit) are allowed to execute normally when MSR_{GS,PR} = 0b10.

41 **Disable MAS Interrupt Updates for Hypervisor** (DMIUH)
   [Category: Embedded.Hypervisor]
   Controls whether MAS registers are updated by hardware when a Data or Instruction TLB Error Interrupt or a Data or Instruction Storage Interrupt is taken in the hypervisor.
   0 MAS registers are set as described in Table 11 on page 1116 when a Data or Instruction TLB Error Interrupt or a Data or Instruction Storage Interrupt is taken in the hypervisor.
   1 MAS registers updates as described in Table 11 are disabled and MAS registers are left unchanged when a Data or Instruction TLB Error Interrupt or a Data or Instruction Storage Interrupt is taken in the hypervisor.

42 **Performance Monitor Interrupt Directed to Guest State** (PMGS)
   [Category: Embedded.Hypervisor]
   [Corequisite Category: Embedded.Performance Monitor]
   Controls whether a Performance Monitor Interrupt that occurs in the guest state is taken in the guest supervisor state or the hypervisor.
   0 Performance Monitor Interrupts that occur in the guest state are directed to the hypervisor state.
   1 Performance Monitor Interrupts that occur in the guest state are directed to the guest supervisor state.

43-63 Reserved
   This register is hypervisor privileged.

---

**Engineering Note**
EPCR only needs to be implemented if Category: Embedded.Hypervisor or category 64-bit are implemented.
4.3 Branch Facility Instructions

4.3.1 System Linkage Instructions

These instructions provide the means by which a program can call upon the system to perform a service, and by which the system can return from performing a service or from processing an interrupt.

The System Call instruction is described in Book I, but only at the level required by an application programmer. A complete description of this instruction appears below.

### System Call SC-form

<table>
<thead>
<tr>
<th>17</th>
<th>11</th>
<th>6</th>
<th>20</th>
<th>27</th>
<th>0</th>
<th>6</th>
<th>11</th>
<th>6</th>
<th>20</th>
<th>27</th>
<th>0</th>
</tr>
</thead>
</table>

sc LEV

[Category: Embedded.Hypervisor]

If LEV = 0 then

1. If MSRGS = 1 then
   - GSR0 ← iax CIA + 4
   - GSR1 ← MSR
   - If IVORs supported then
     - NIA ← GIVP0:47 || GIVOR848:59 || 0b0000
   - Else
     - NIA ← GIVP0:51 || 0x0120
     - MSR ← new_value (see below)

2. Else
   - SRR0 ← iax CIA + 4
   - SRR1 ← MSR
   - If IVORs supported then
     - NIA ← IVP0:47 || IVOR848:59 || 0b0000
   - Else
     - NIA ← IVP0:51 || 0x0120
     - MSR ← new_value (see below)

If LEV = 1 then

1. SRR0 ← iax CIA + 4
2. SRR1 ← MSR
3. If IVORs supported then
   - NIA ← IVP0:47 || IVOR4048:59 || 0b0000
4. Else
   - NIA ← IVP0:51 || 0x300
   - MSR ← new_value (see below)

If category E.HV is not implemented, the System Call instruction behaves as if MSRGS = 0 and LEV = 0.

If MSRGS = 0 or if LEV = 1, the effective address of the instruction following the System Call instruction is placed into SRR0 and the contents of the MSR are copied into SRR1. Otherwise, the effective address of the instruction following the System Call instruction is placed into GSRR0 and the contents of the MSR are copied into GSRR1.

If LEV=0, a System Call interrupt is generated. If LEV=1, an Embedded Hypervisor System Call interrupt is generated. The interrupt causes the MSR to be set as described in Section 7.6.10 and Section 7.6.30.

If LEV=0 and the thread is in guest state, the interrupt causes the next instruction to be fetched from the effective address based on one of the following:

- GIVP0:47||GIVOR848:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- GIVP0:51||0x120 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

If LEV=0 and the thread is in hypervisor state, the interrupt causes the next instruction to be fetched from the effective address based on one of the following:

- IVP0:47||IVOR848:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVP0:51||0x120 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

If LEV=1, the interrupt causes the next instruction to be fetched from the effective address based on one of the following:

- IVP0:47||IVOR4048:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVP0:51||0x300 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

This instruction is context synchronizing.

**Special Registers Altered:**

<table>
<thead>
<tr>
<th>SRR0</th>
<th>GSRR0</th>
<th>SRR1</th>
<th>GSRR1</th>
<th>MSR</th>
</tr>
</thead>
</table>

**Programming Note**

`sc` serves as both a basic and an extended mnemonic. The Assembler will recognize an `sc` mnemonic with one operand as the basic form, and an `sc` mnemonic with no operand as the extended form. In the extended form, the LEV operand is omitted and assumed to be 0.
Return From Interrupt  XL-form

rfi

<table>
<thead>
<tr>
<th>19</th>
<th>///</th>
<th>///</th>
<th>///</th>
<th>50</th>
</tr>
</thead>
</table>

MSR ← SRR1  
NIA ←lea SRR0:61 || 0b00

The *rfi* instruction is used to return from a base class interrupt, or as a means of simultaneously establishing a new context and synchronizing on that new context.

The contents of SRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address SRR0:61||0b00. (Note: VLE behavior may be different; see Book VLE.) If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into the applicable save/restore register 0 by the interrupt processing mechanism (see Section 7.6 on page 1161) is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in SRR0 at the time of the execution of the *rfi*).

This instruction is privileged and context synchronizing.

Category: Embedded, Hypervisor

When *rfi* is executed in guest state, the instruction is mapped to *rfgi* and *rfgi* is executed instead.

Special Registers Altered:

MSR

Return From Critical Interrupt  XL-form

rfci

<table>
<thead>
<tr>
<th>19</th>
<th>///</th>
<th>///</th>
<th>///</th>
<th>51</th>
</tr>
</thead>
</table>

MSR ← CSRR1  
NIA ←lea CSRR0:61 || 0b00

The *rfci* instruction is used to return from a critical class interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously.

The contents of CSRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address CSRR0:61||0b00. (Note: VLE behavior may be different; see Book VLE.) If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0 or CSRR0 by the interrupt processing mechanism (see Section 7.6 on page 1161) is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in CSRR0 at the time of the execution of the *rfci*).

This instruction is hypervisor privileged and context synchronizing.

Special Registers Altered:

MSR
Return From Debug Interrupt X-form

rfdi

[Category: Embedded.Enhanced Debug]

\[
\begin{array}{cccccccc}
\text{MSR} & \leftarrow & \text{DSRR1} \\
\text{NIA} & \leftarrow & \text{iea} & \text{DSRR0}^{0.61} & || & 0b00
\end{array}
\]

The `rfdi` instruction is used to return from a Debug interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously.

The contents of DSRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address DSRR0^{0.61}||0b00. (Note: VLE behavior may be different; see Book VLE.) If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, CSRR0, or DSRR0 by the interrupt processing mechanism is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in DSRR0 at the time of the execution of the `rfdi`).

This instruction is hypervisor privileged and context synchronizing.

**Special Registers Altered:**

- MSR

---

Return From Machine Check Interrupt XL-form

rfmci

\[
\begin{array}{cccccccc}
\text{MSR} & \leftarrow & \text{MCSRR1} \\
\text{NIA} & \leftarrow & \text{iea} & \text{MCSRR0}^{0.61} & || & 0b00
\end{array}
\]

The `rfmci` instruction is used to return from a Machine Check class interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously.

The contents of MCSRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address MCSRR0^{0.61}||0b00. (Note: VLE behavior may be different; see Book VLE.) If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, CSRR0, MCSRR0, or DSRR0 by the interrupt processing mechanism (see Section 7.6 on page 1161) is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in MCSRR0 at the time of the execution of the `rfmci`).

This instruction is hypervisor privileged and context synchronizing.

**Special Registers Altered:**

- MSR
Return From Guest Interrupt  

**Return From Guest Interrupt**  

```
rfgi  [Category:Embedded.Hypervisor]
```

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>19</td>
<td>102</td>
</tr>
</tbody>
</table>

The `rfgi` instruction is used to return from a guest state base class interrupt, or as a means of simultaneously establishing a new context and synchronizing on that new context.

The contents of Guest Save/Restore Register 1 are placed into the MSR. If the `rfgi` is executed in the guest supervisor state (MSRGS PR = 0b10), the bit MSR GS is not modified and the bits MSR UCLE DE PMM are modified only if the associated bits in the Machine State Register Protect (MSRP) Register are set to 0. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address GSRR0:61||0b00. (Note: VLE behavior may be different; see Book VLE.) If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into the associated save/restore register 0 by the interrupt processing mechanism is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in GSRR0 at the time of the execution of the `rfgi`).

This instruction is privileged and context synchronizing.

**Special Registers Altered:**

- MSR

Embedded Hypervisor Privilege  

**Embedded Hypervisor Privilege**  

```
ehpriv  OC  [Category: Embedded.Hypervisor]
```

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td>270</td>
</tr>
</tbody>
</table>

The `ehpriv` instruction generates an Embedded Hypervisor Privilege Exception resulting in an Embedded Hypervisor Privilege Interrupt.

The OC field may be used by hypervisor software to provide a facility for emulated virtual instructions.

**Special Registers Altered:**

- None

---

**Programming Note**

The `ehpriv` instruction is analogous to a guaranteed illegal instruction encoding in that it guarantees that an Embedded Hypervisor Privilege exception is generated. The instruction is useful for programs that need to communicate information to the hypervisor software, particularly as a means for implementing breakpoint operations in a hypervisor managed debugger.

---

**Programming Note**

`ehpriv` serves as both a basic and an extended mnemonic. The Assembler will recognize an `ehpriv` mnemonic with one operand as the basic form, and an `ehpriv` mnemonic with no operand as the extended form. In the extended form, the OC operand is omitted and assumed to be 0.
Chapter 5. Fixed-Point Facility

5.1 Fixed-Point Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Fixed-Point Facility that are not covered in Book I.

5.2 Special Purpose Registers

Special Purpose Registers (SPRs) are read and written using the `mfspr` (page 1054) and `mtspr` (page 1053) instructions. Most SPRs are defined in other chapters of this book; see the index to locate those definitions.

5.3 Fixed-Point Facility Registers

5.3.1 Processor Version Register

The Processor Version Register (PVR) is a 32-bit read-only register that contains a value identifying the version and revision level of the hardware. The contents of the PVR can be copied to a GPR by the `mfspr` instruction. Read access to the PVR is privileged; write access is not provided.

The PVR distinguishes between implementations that differ in attributes that may affect software. It contains two fields.

<table>
<thead>
<tr>
<th>Bit Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Version</td>
<td>A 16-bit number that identifies the version of the implementation. Different version numbers indicate major differences between implementations, such as which optional facilities and instructions are supported.</td>
</tr>
<tr>
<td>Revision</td>
<td>A 16-bit number that distinguishes between implementations of the version. Different revision numbers indicate minor differences between implementations having the same version number, such as clock rate and Engineering Change level.</td>
</tr>
</tbody>
</table>

Version numbers are assigned by the Power ISA Architecture process. Revision numbers are assigned by an implementation-defined process.

5.3.2 Chip Information Register

The Chip Information Register (CIR) is a 32-bit read-only register that contains a value identifying the manufacturer and other characteristics of the chip on which the processor is implemented. The contents of the CIR can be copied to a GPR by the `mfspr` instruction. Read access to the CIR is privileged; write access is not provided.

![Figure 11. Chip Information Register](image)

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:35</td>
<td>Manufacturer ID (ID) A four-bit field that identifies the manufacturer of the chip.</td>
</tr>
<tr>
<td>36:63</td>
<td>Implementation-dependent.</td>
</tr>
</tbody>
</table>

5.3.3 Processor Identification Register

The Processor Identification Register (PIR) is a 32-bit register that contains a value that can be used to distinguish the thread from other threads in the system. The contents of the PIR can be read using `mfspr` and written using `mtspr`. Read access to the PIR is privileged; write access, if provided, is hypervisor privileged.
Read accesses to the PIR in guest supervisor state are mapped to the GPIR. The means by which the PIR is initialized are implementation-dependent. The PIR can be used to identify the thread globally among all threads in a system that contains multiple threads. This facilitates more efficient usage of the Processor Control facility (see Section 11).

5.3.4 Guest Processor Identification Register [Category: Embedded.Hypervisor]

The Guest Processor Identification Register (GPIR) is a 32-bit register that contains a value that can be used to distinguish the thread from other threads in the system. The contents of the GPIR can be read using mfspr and written using mtspr. Read access to the GPIR is privileged; write access, if provided, is hypervisor privileged. Some previous implementations did not allow write access to the PIR. This allows the hypervisor to easily track changes to the GPIR. If write access is allowed to the PIR, write access should be allowed to the GPIR and should only be available to the hypervisor.

Programming Note

mfspr RT,PIR should be used to read GPIR in guest supervisor state. See Section 2.2.1, “Register Mapping”.

5.3.5 Program Priority Register

32-bit

Privileged programs may set a wider range of program priorities in the PRI field of PPR32 than may be set by problem-state programs (see Section 3.1 of Book II). Problem-state programs may only set values in the range of 0b010 to 0b100. Privileged programs may set values in the range of 0b001 to 0b110. Hypervisor software may also set 0b111. If a program attempts to set a value that is not available to it, the PRI field remains unchanged. The values and their corresponding meanings are as follows.

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>001</td>
<td>very low</td>
</tr>
<tr>
<td>010</td>
<td>low</td>
</tr>
<tr>
<td>011</td>
<td>medium low</td>
</tr>
<tr>
<td>100</td>
<td>medium</td>
</tr>
<tr>
<td>101</td>
<td>medium high</td>
</tr>
<tr>
<td>110</td>
<td>high</td>
</tr>
<tr>
<td>111</td>
<td>very high</td>
</tr>
</tbody>
</table>

5.3.6 Software-use SPRs

Software-use SPRs are 64-bit registers provided for use by software.

<table>
<thead>
<tr>
<th>SPRG0</th>
<th>SPRG1</th>
<th>SPRG2</th>
<th>SPRG3</th>
<th>SPRG4</th>
<th>SPRG5</th>
<th>SPRG6</th>
<th>SPRG7</th>
<th>SPRG8</th>
</tr>
</thead>
</table>

0 through SPRG2

USPRG0 was made a 32-bit register and renamed to VRSAVE; see Sections 3.2.3 and 5.3.3 of Book I.
These 64-bit registers can be accessed only in supervisor mode.

[Category:Embedded.Hypervisor]
Access to these registers in guest supervisor state is mapped to GSPRG0 through GSPRG2.

SPRG3
This 64-bit register can be read in supervisor mode and can be written only in supervisor mode. It is implementation-dependent whether or not this register can be read in user mode.

[Category:Embedded.Hypervisor]
Access to this register in guest state is mapped to GSPRG3.

SPRG4 through SPRG7
These 64-bit registers can be written only in supervisor mode. These registers can be read in supervisor and user modes.

SPRG8 through SPRG9
These 64-bit registers can be accessed only in supervisor mode.

---

**Programming Note**
The intended use for SPRG9 is for internal debug exception handling.

---

GSPRG0 through GSPRG2

[Category:Embedded.Hypervisor]
These 64-bit registers can be accessed only in supervisor mode.

GSPRG3

[Category:Embedded.Hypervisor]
This 64-bit register can be read in supervisor mode and can be written only in supervisor mode. If an implementation permits problem state read access to SPRG3, the problem state read access is remapped to GSPRG3.

SPRGi or GSPRGi can be read using `mfspr` and written using `mtspr`.

---

**Programming Note**

`mfspr RT,SPRGi` should be used to read GSPRGi in guest state. `mtspr SPRGi,RS` should be used to write GSPRGi in guest state. See Section 2.2.1, “Register Mapping”.
5.3.7 External Process ID Registers [Category: Embedded.External PID]

The External Process ID Registers provide capabilities for loading and storing General Purpose Registers and performing cache management operations using a supplied context other than the context normally used by the programming model.

Two SPRs describe the context for loading and storing using external contexts. The External Process ID Load Context (EPLC) Register provides the context for External Process ID Load instructions, and the External Process ID Store Context (EPSC) Register provides the context for External Process ID Store instructions. Each of these registers contains a PR (privilege) bit, an AS (address space) bit, a Process ID, a GS (guest state) bit <E.HV>, and an LPID <E.HV>. Changes to the EPLC or the EPSC Register require that a context synchronizing operation be performed prior to using any External Process ID instructions that use these registers.

External Process ID instructions that use the context provided by the EPLC register include lbepx, lhepx, lwepx, ldepx, dcbtep, dcbfep, icbtep, Ifdepx, evlddepx, lvpx, and lvpxl and those that use the context provided by the EPSC register include stbepx, sthepx, stwepx, stdepx, dcbzep, stfdepx, evstddepx, stvepx, stvepxl, and dcbtstep. Instruction definitions appear in Section 5.4.3.

System software configures the EPLC register to reflect the Process ID, AS, PR, GS <E.HV>, and LPID <E.HV> state from the context that it wishes to perform loads from and configures the EPSC register to reflect the Process ID, AS, PR, GS <E.HV>, and LPID <E.HV> state from the context it wishes to perform stores to. Software then issues External Process ID instructions to manipulate data as required.

When the an External Process ID Load instruction is executed, it uses the context information in the EPLC Register instead of the normal context with respect to address translation and storage access control. EPLC<PR> is used in place of MSR<PR>, EPLC<AS> is used in place of MSR<AS>, EPLC<GS> is used in place of MSR<GS>, EPLC<LPID> is used in place of LPIDR <E.HV>, and EPLC<ELS> is used in place of LPIDR <E.HV>. Similarly, when the an External Process ID Store instruction is executed, it uses the context information in the EPSC Register instead of the normal context with respect to address translation and storage access control. EPSC<PR> is used in place of MSR<PR>, EPSC<AS> is used in place of MSR<AS>, EPSC<GS> is used in place of MSR<GS>, EPSC<ELS> is used in place of LPIDR <E.HV>, and EPSC<ELS> is used in place of LPIDR <E.HV>. Translation occurs using the new substituted values.

If the TLB lookup is successful, the storage access control mechanism grants or denies the access using context information from EPLC<PR> or EPSC<PR> for loads and stores respectively. If access is not granted, a Data Storage interrupt occurs, and the ESR<PID> bit is set to 1. If the operation was a Store, the ESR<ST> bit is also set to 1.

5.3.7.1 External Process ID Load Context (EPLC) Register

The EPLC register contains fields to provide the context for External Process ID Load instructions.

Figure 15. External Process ID Load Context Register

These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bit</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td><strong>External Load Context PR Bit</strong> (EPR)</td>
</tr>
<tr>
<td></td>
<td>Used in place of MSR&lt;PR&gt; by the storage access control mechanism when an External Process ID Load instruction is executed.</td>
</tr>
<tr>
<td>0</td>
<td>Supervisor mode</td>
</tr>
<tr>
<td>1</td>
<td>User mode</td>
</tr>
<tr>
<td>33</td>
<td><strong>External Load Context AS Bit</strong> (EAS)</td>
</tr>
<tr>
<td></td>
<td>Used in place of MSR&lt;AS&gt; for translation when an External Process ID Load instruction is executed, and, if this Load instruction causes a Data TLB Error interrupt, loaded into MAS registers in place of MSR&lt;AS&gt;:</td>
</tr>
<tr>
<td>0</td>
<td>Address space 0</td>
</tr>
<tr>
<td>1</td>
<td>Address space 1</td>
</tr>
<tr>
<td>34</td>
<td><strong>External Load Context GS Bit</strong> (EGS)</td>
</tr>
<tr>
<td></td>
<td>[Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Used in place of MSR&lt;GS&gt; for translation when an External Process ID Load instruction is executed.</td>
</tr>
<tr>
<td>0</td>
<td>Hypervisor state</td>
</tr>
<tr>
<td>1</td>
<td>Guest state</td>
</tr>
</tbody>
</table>

**Programming Note**

When a mtsprr instruction is executed that targets EPLC, the EGS and ELPD fields are only modified if the thread is in hypervisor state.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>35</td>
<td>Reserved</td>
</tr>
<tr>
<td>36:47</td>
<td><strong>External Load Context LPID Value</strong> (ELPID)</td>
</tr>
<tr>
<td></td>
<td>[Category: Embedded.Hypervisor]</td>
</tr>
<tr>
<td></td>
<td>Used in place of LPIDR register for translation</td>
</tr>
</tbody>
</table>
when an External Process ID Load instruction is executed.

**Programming Note**

When a `mtspr` instruction is executed that targets EPLC, the EGS and ELPID fields are only modified if the thread is in hypervisor state.

<table>
<thead>
<tr>
<th>Bit Range</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>48:49</td>
<td>Reserved</td>
</tr>
<tr>
<td>50:63</td>
<td>External Load Context Process ID Value (EPID) Used in place of the Process ID register value for translation when an external Process ID Load instruction is executed, and, if this Load instruction causes a Data TLB Error interrupt, loaded into MAS registers in place of PID contents.</td>
</tr>
</tbody>
</table>

### 5.3.7.2 External Process ID Store Context (EPSC) Register

The EPSC register contains fields to provide the context for External Process ID Store instructions. The field encoding is the same as the EPLC Register.

![Figure 16. External Process ID Store Context Register](image)

These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bits</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td><strong>External Store Context PR Bit</strong> (EPR) Used in place of MSRPR by the storage access control mechanism when an External Process ID Store instruction is executed. 0 Supervisor mode 1 User mode</td>
</tr>
<tr>
<td>33</td>
<td><strong>External Store Context AS Bit</strong> (EAS) Used in place of MSRD for translation when an External Process ID Store instruction is executed, and, if this Store instruction causes a Data TLB Error interrupt, loaded into MAS registers in place of MSRD. 0 Address space 0 1 Address space 1</td>
</tr>
<tr>
<td>34</td>
<td><strong>External Store Context GS Bit</strong> (EGS) [Category: Embedded,Hypervisor] Used in place of MSRGS for translation when an External Process ID Store instruction is executed. 0 Hypervisor state 1 Guest state</td>
</tr>
</tbody>
</table>

**Programming Note**

When a `mtspr` instruction is executed that targets EPSC, the EGS and ELPID fields are only modified if the thread is in hypervisor state.

<table>
<thead>
<tr>
<th>Bit Range</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>48:49</td>
<td>Reserved</td>
</tr>
<tr>
<td>50:63</td>
<td>External Store Context Process ID Value (EPID) Used in place of LPIDR register for translation when an External Process ID Store instruction is executed.</td>
</tr>
</tbody>
</table>

**Programming Note**

When a `mtspr` instruction is executed that targets EPSC, the EGS and ELPID fields are only modified if the thread is in hypervisor state.

<table>
<thead>
<tr>
<th>Bit Range</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>48:49</td>
<td>Reserved</td>
</tr>
<tr>
<td>50:63</td>
<td><strong>External Store Context Process ID Value (EPID)</strong> Used in place of the Process ID register value for translation when an external PID Store instruction is executed, and, if this Store instruction causes a Data TLB Error interrupt, loaded into MAS registers in place of PID contents.</td>
</tr>
</tbody>
</table>
5.4 Fixed-Point Facility Instructions

5.4.1 Move To/From System Register Instructions

The Move To Special Purpose Register and Move From Special Purpose Register instructions are described in Book I, but only at the level available to an application programmer. For example, no mention is made there of registers that can be accessed only in supervisor mode. The descriptions of these instructions given below extend the descriptions given in Book I, but do not list Special Purpose Registers that are implementation-dependent. In the descriptions of these instructions given below, the “defined” SPR numbers are the SPR numbers shown in Table 17 and the implementation-specific SPR numbers that are implemented, and similarly for “defined” registers.

Extended mnemonics

Extended mnemonics are provided for the \texttt{mtspr} and \texttt{mfspr} instructions so that they can be coded with the SPR name as part of the mnemonic rather than as a numeric operand; see Appendix B.

<table>
<thead>
<tr>

</table>

- This register is not defined for this instruction.
1 See Section 1.3.5 of Book I. If multiple categories are listed separated by a semicolon, all the listed categories must be implemented in order for the other columns of the line to apply. A comma separates two alternatives, and takes precedence over a semicolon; e.g., the EPCR (E.HV,E;64) must be implemented if either (a) category E.HV is implemented or (b) the implementation is Embedded and supports the 64-bit category.
2 This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2 of Book III-E).
3 This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state; see Chapter 2 of Book III-E. Otherwise, the register is privileged.
4 The register can be written by the \texttt{dcread} instruction.
5 The register can be written by the \texttt{icread} instruction.
6 The register is Category: Phased-in.
7 If the Embedded.Hypervisor category is supported, this register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2 of Book III-E). Otherwise, the register is privileged.
8 The register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state, and guest references to the register are redirected to the corresponding guest register (see Chapter 2 of Book III-E). Otherwise the register is privileged.
9 Accesses to these SPRs are noops; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I.

\]

\[
n \leftarrow \text{spr}_{5:9} | | \text{spr}_{0:4}
\]

\[
\text{switch (n)}
\begin{align*}
\text{case (808, 809, 810, 811):} & \\
\text{default:} & \\
\text{if length(SPR(n)) = 64 then} & \\
\text{SPR(n) } \leftarrow (\text{RS}) & \\
\text{else} & \\
\text{SPR(n) } \leftarrow (\text{RS})_{32:63}
\end{align*}
\]

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 17. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of register RS are placed into the designated Special Purpose Register. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RS are placed into the SPR.

For this instruction, SPRs TBL and TBU are treated as separate 32-bit registers; setting one leaves the other unaltered.

\[\text{spr}_0=1\] if and only if writing the register is privileged. Execution of this instruction specifying a defined and privileged register when MSRPR=1 causes a Privileged Instruction type Program interrupt.

Execution of this instruction specifying an SPR number that is not defined for the implementation causes either an Illegal Instruction type Program interrupt or one of the following.

- if \[\text{spr}_0=0\]: boundedly undefined results
- if \[\text{spr}_0=1\]:
  - if MSRPR=1: Privileged Instruction type Program interrupt; if MSRPR=0: boundedly undefined results

If the SPR number is set to a value that is shown in Figure 17 but corresponds to an optional Special Purpose Register that is not provided by the implementation, the effect of executing this instruction is the same as if the SPR number were reserved.

Special Registers Altered:
See Figure 17

---

**Compiler and Assembler Note**

For the \text{mtspr} and \text{mfspr} instructions, the SPR number coded in assembler language does not appear directly as a 10-bit binary number in the instruction. The number coded is split into two 5-bit halves that are reversed in the instruction, with the high-order 5 bits appearing in bits 16:20 of the instruction and the low-order 5 bits in bits 11:15.

**Programming Note**

For a discussion of software synchronization requirements when altering certain Special Purpose Registers, see Chapter 12, “Synchronization Requirements for Context Alterations” on page 1235.

\text{RT } \leftarrow 32 \quad || \quad \text{SPR(n)}
\]

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 17. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of the designated Special Purpose Register are placed into register RT. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RT receive the contents of the Special Purpose Register and the high-order 32 bits of RT are set to zero.

spr0=1 if and only if reading the register is privileged. Execution of this instruction specifying a defined and privileged register when MSRPR=1 causes a Privileged Instruction type Program interrupt.

| RT | spr | 339 | / |

Move To Device Control Register
XFX-form

mtdcr DCRN,RS

\[ \text{DCRN } \leftarrow \text{dcr}_{5:9} || \text{dcr}_{0:4} \]
\[ \text{DCR(DCRN) } \leftarrow (RS) \]

Let DCRN denote a Device Control Register. (The supported Device Control Registers are implementation-dependent.)

The contents of register RS are placed into the designated Device Control Register. For 32-bit Device Control Registers, the contents of bits 32:63 of (RS) are placed into the Device Control Register.

This instruction is privileged.

Special Registers Altered:
   Implementation-dependent.

Move To Device Control Register Indexed
X-form

mtdcrx RA,RS

\[ \text{mtdcrx 105,r2} \]
\[ \text{mtdcrux r1,r2} \]

Let the contents of register RA denote a Device Control Register. (The supported Device Control Registers supported are implementation-dependent.)

The contents of register RS are placed into the designated Device Control Register. For 32-bit Device Control Registers, the contents of bits 32:63 of (RS) are placed into the Device Control Register.

The specification of Device Control Registers using mtdcrx, mtdcrux (see Book I), and mtdcr is implementation-dependent. For example, mtdcr 105,r2 and mtdcrx 1,r2 (where register r1 contains the value 105) may not produce identical results on an implementation.

This instruction is privileged.

Special Registers Altered:
   Implementation-dependent.
Move From Device Control Register
XFX-form

\[ \text{mfdcr} \quad \text{RT,DCRN} \]

[Category: Embedded.Device Control]

\[
\begin{array}{cccccc}
31 & \text{RT} & 21 &  \text{dcr} & 323 & / \\
0 & 6 & 11 & & 21 & 31
\end{array}
\]

\[
\text{DCRN} \leftarrow \text{dcr}_{5:9} \parallel \text{dcr}_{0:4}
\]

RT \leftarrow \text{DCR(DCRN)}

Let DCRN denote a Device Control Register. (The supported Device Control Registers are implementation-dependent.)

The contents of the designated Device Control Register are placed into register RT. For 32-bit Device Control Registers, the contents of the Device Control Register are placed into bits 32:63 of RT. Bits 0:31 of RT are set to 0.

This instruction is privileged.

Special Registers Altered:
Implementation-dependent.

Move From Device Control Register
Indexed X-form

\[ \text{mfdr} \quad \text{RT,RA} \]

[Category: Embedded.Device Control]

\[
\begin{array}{ccccccc}
31 & \text{RT} & \text{RA} & \text{dcr} & 259 & / \\
0 & 6 & 11 & 16 & 21 & 31
\end{array}
\]

\[
\text{DCRN} \leftarrow \text{(RA)}
\]

RT \leftarrow \text{DCR(DCRN)}

Let the contents of register RA denote a Device Control Register (the supported Device Control Registers are implementation-dependent.)

The contents of the designated Device Control Register are placed into register RT. For 32-bit Device Control Registers, the contents of bits 32:63 of the designated Device Control Register are placed into RT. Bits 0:31 of RT are set to 0.

The specification of Device Control Registers using \text{mfdcr}x and \text{mfdcr}ux (see Book I) compared to the specification of Device Control Registers using \text{mfdcr} is implementation-dependent. For example, \text{mfdcr} r2,105 and \text{mfdcr}x r2,r1 (where register r1 contains the value 105) may not produce identical results on an implementation or between implementations. Also, accessing privileged Device Control Registers in supervisor mode with \text{mfdcr}ux is implementation-dependent.

This instruction is privileged.

Move To Machine State Register
X-form

\[ \text{mtmsr} \quad \text{RS} \]

\[
\begin{array}{cccccc}
31 & \text{RS} & 16 & 21 & 146 & / \\
0 & 6 & 11 & 16 & 21 & 31
\end{array}
\]

\[
\text{newmsr} \leftarrow \text{(RS)}_{32:63}
\]

if MSR_{CM} = 0 \& newmsr_{CM} = 1 then \text{NIA}_{0:31} \leftarrow 0

if MSR_{GS} = 1 then

\[
\begin{array}{l}
\text{newmsr}_{WE} \leftarrow \text{MSR}_{GS} \text{ WE} \\
\text{prots}_{0:31} \leftarrow 0 \\
\text{prots}_{UCLEP \text{ DEP PMMP}} \leftarrow \text{MSR}_{UCLEP \text{ DEP PMMP}} \\
\text{newmsr} \leftarrow \text{prots} \& \text{MSR} \mid \text{-prots} \& \text{newmsr} \\
\text{MSR} \leftarrow \text{newmsr}
\end{array}
\]

The contents of register RS_{32:63} are placed into the MSR. If the thread is changing from 32-bit mode to 64-bit mode, the next instruction is fetched from 320||\text{NIA}_{32:63}.

This instruction is privileged and execution synchronizing.

In addition, alterations to the EE or CE bits are effective as soon as the instruction completes. Thus if MSR_{EE}=0 and an External interrupt is pending, executing an \text{mtmsr} that sets MSR_{EE} to 1 will cause the External interrupt to be taken before the next instruction is executed, if no higher priority exception exists. Likewise, if MSR_{CE}=0 and a Critical Input interrupt is pending, executing an \text{mtmsr} that sets MSR_{CE} to 1 will cause the Critical Input interrupt to be taken before the next instruction is executed if no higher priority exception exists. (See Section 7.6 on page 1161.)

[Category: Embedded.Hypervisor]
GS, WE and bits protected with MSRP are only modified if \text{mtmsr} is executed in hypervisor state.

Special Registers Altered:
MSR

Programming Note
For a discussion of software synchronization requirements when altering certain MSR bits please refer to Chapter 12.
Move From Machine State Register X-form

**mfmsr RT**

\[
\begin{array}{cccccc}
& 31 & 6 & 11 & 16 & 21 & 83 & / \\
0 & & & & & & & \\
\end{array}
\]

\[
RT \leftarrow 32 \parallel MSR
\]

The contents of the MSR are placed into bits 32:63 of register RT and bits 0:31 of RT are set to 0.

This instruction is privileged.

**Special Registers Altered:**

None

---

Write MSR External Enable X-form

**wrtee RS**

\[
\begin{array}{cccccc}
& 31 & 6 & 11 & 16 & 21 & 131 & / \\
0 & & & & & & & \\
\end{array}
\]

\[
MSR_{EE} \leftarrow (RS)_{48}
\]

The content of (RS)_{48} is placed into MSR_{EE}.

Alteration of the MSR_{EE} bit is effective as soon as the instruction completes. Thus if MSR_{EE}=0 and an External interrupt is pending, executing a wrtee instruction that sets MSR_{EE} to 1 will cause the External interrupt to occur before the next instruction is executed, if no higher priority exception exists (Section 7.9, “Exception Priorities” on page 1190).

This instruction is privileged.

**Special Registers Altered:**

MSR
Write MSR External Enable Immediate
X-form

wrteei E

MSR_EE ← E

The value specified in the E field is placed into MSR_EE.

Alteration of the MSR_EE bit is effective as soon as the
instruction completes. Thus if MSR_EE=0 and an External
interrupt is pending, executing a wrtee instruction
that sets MSR_EE to 1 will cause the External interrupt to
occur before the next instruction is executed, if no
higher priority exception exists (Section 7.9, “Exception
Priorities” on page 1190).

This instruction is privileged.

Special Registers Altered:
MSR

\(^1\) If the Embedded.Hypervisor category is supported, this value is hypervisor privileged. Otherwise, the value is privileged.

Figure 18. Priority levels for or Rx,Rx,Rx
5.4.3 External Process ID Instructions [Category: Embedded.External PID]

*External Process ID* instructions provide capabilities for loading and storing General Purpose Registers and performing cache management operations using a supplied context other than the context normally used by translation.

The EPLC and EPSC registers provide external contexts for performing loads and stores. The EPLC and the EPSC registers are described in Section 5.3.7.

If an Alignment interrupt, Data Storage interrupt, or a Data TLB Error interrupt, occurs while attempting to execute an *External Process ID* instruction, ESR_{EPI}D is set to 1 indicating that the instruction causing the interrupt was an *External Process ID* instruction; any other applicable ESR bits are also set.

---

**Load Byte by External Process ID Indexed X-form**

\[
\text{lbepx} \quad \text{RT,RA,RB}
\]

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| RT | RA | RB | 95 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 |

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
RT ← \text{MEM}(EA,1)

Let the effective address (EA) be the sum (RA|0)+(RB). The byte in storage addressed by EA is loaded into RT_{56:63}. RT_{0:55} are set to 0.

For *lbepx*, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLC_{EPR} is used in place of MSR_{PR}
- EPLC_{EAS} is used in place of MSR_{DS}
- EPLC_{EPI}D is used in place of PID
- EPLC_{EGS} is used in pace of MSR_{GS} <E.HV>
- EPLC_{ELPID} is used in pace of LPIDR <E.HV>

This instruction is privileged.

**Special Registers Altered:**
None

**Programming Note**
This instruction behaves identically to a *lbzx* instruction except for using the EPLC register to provide the translation context.

---

**Load Halfword by External Process ID Indexed X-form**

\[
\text{lhepx} \quad \text{RT,RA,RB}
\]

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

| RT | RA | RB | 287 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 |

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
RT ← \text{MEM}(EA,2)

Let the effective address (EA) be the sum (RA|0)+(RB). The halfword in storage addressed by EA is loaded into RT_{48:63}. RT_{0:47} are set to 0.

For *lhepx*, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLC_{EPR} is used in place of MSR_{PR}
- EPLC_{EAS} is used in place of MSR_{DS}
- EPLC_{EPI}D is used in place of PID
- EPLC_{EGS} is used in pace of MSR_{GS} <E.HV>
- EPLC_{ELPID} is used in pace of LPIDR <E.HV>

This instruction is privileged.

**Special Registers Altered:**
None

**Programming Note**
This instruction behaves identically to a *lhzx* instruction except for using the EPLC register to provide the translation context.
Load Word by External Process ID
Indexed X-form

lwepx  RT,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
RT ← 32:0 | MEM(EA, 4)

Let the effective address (EA) be the sum (RA|0)+(RB). The word in storage addressed by EA is loaded into RT32:63. RT0:31 are set to 0.

For lwepx, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRS
- EPLCEPID is used in place of PID
- EPLCEEGS is used in place of MSRGS <E.HV>
- EPLCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

Special Registers Altered:
None

Programming Note
This instruction behaves identically to a lwzx instruction except for using the EPLC register to provide the translation context.

Load Doubleword by External Process ID
Indexed X-form

ldepx  RT,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
RT ← MEM(EA, 8)

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into RT.

For ldepx, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRS
- EPLCEPID is used in place of PID
- EPLCEEGS is used in place of MSRGS <E.HV>
- EPLCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

Corequisite Categories:
64-Bit

Special Registers Altered:
None

Programming Note
This instruction behaves identically to a ldx instruction except for using the EPLC register to provide the translation context.
Store Byte by External Process ID
Indexed X-form

stbepx RS,RA,RB

\[
\begin{array}{cccc|c}
31 & RS & RA & RB & 223 \\
\end{array}
\]

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
MEM(EA,1) ← (RS)_{56:63}

Let the effective address (EA) be the sum (RA|0)+(RB). (RS)_{56:63} are stored into the byte in storage addressed by EA.

For \textit{stbepx}, the normal translation mechanism is not used. The contents of the EPSC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:
EPSC\textsubscript{EPR} is used in place of MSR\textsubscript{PR}
EPSC\textsubscript{EAS} is used in place of MSR\textsubscript{DS}
EPSC\textsubscript{EPID} is used in place of PID
EPSC\textsubscript{EGS} is used in place of MSR\textsubscript{GS}<E.HV>
EPSC\textsubscript{ELPID} is used in place of LPIDR<E.HV>

This instruction is privileged.

Special Registers Altered:
None

Programming Note

This instruction behaves identically to a \textit{stbx} instruction except for using the EPSC register to provide the translation context.

Store Halfword by External Process ID
Indexed X-form

sthexp RS,RA,RB

\[
\begin{array}{cccc|c}
31 & RS & RA & RB & 415 \\
\end{array}
\]

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
MEM(EA,2) ← (RS)_{48:63}

Let the effective address (EA) be the sum (RA|0)+(RB). (RS)_{48:63} are stored into the halfword in storage addressed by EA.

For \textit{sthexp}, the normal translation mechanism is not used. The contents of the EPSC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:
EPSC\textsubscript{EPR} is used in place of MSR\textsubscript{PR}
EPSC\textsubscript{EAS} is used in place of MSR\textsubscript{DS}
EPSC\textsubscript{EPID} is used in place of PID
EPSC\textsubscript{EGS} is used in place of MSR\textsubscript{GS}<E.HV>
EPSC\textsubscript{ELPID} is used in place of LPIDR<E.HV>

This instruction is privileged.

Special Registers Altered:
None

Programming Note

This instruction behaves identically to a \textit{sthx} instruction except for using the EPSC register to provide the translation context.
Store Word by External Process ID  
Indexed X-form

```
storex  RS,RA,RB

if RA = 0 then b ← 0
else           b ← (RA)
EA ← b + (RB)
MEM(EA,4) ← (RS)_{32:63}
```

Let the effective address (EA) be the sum (RA|0)+(RB). 
(RS)_{32:63} are stored into the word in storage addressed 
by EA.

For `storex`, the normal translation mechanism is not 
used. The contents of the EPSC register are used to 
provide the context in which translation occurs. The fol-
lowing substitutions are made for just the translation 
and access control process:

- EPSCPR is used in place of MSRPR
- EPSCAS is used in place of MSRDS
- EPSCPID is used in place of PID
- EPSCGS is used in pace of MSRGS <E.HV>
- EPSCLPID is used in pace of LPIDR <E.HV>

This instruction is privileged.

**Special Registers Altered:**
None

---

**Programming Note**

This instruction behaves identically to a `stwx` 
instruction except for using the EPSC register to 
provide the translation context.

---

Store Doubleword by External Process ID  
Indexed X-form

```
storepx  RS,RA,RB

if RA = 0 then b ← 0
else           b ← (RA)
EA ← b + (RB)
MEM(EA,8) ← (RS)
```

Let the effective address (EA) be the sum (RA|0)+(RB). 
(RS) is stored into the doubleword in storage 
addressed by EA.

For `storepx`, the normal translation mechanism is not 
used. The contents of the EPSC register are used to 
provide the context in which translation occurs. The fol-
lowing substitutions are made for just the translation 
and access control process:

- EPSCPR is used in place of MSRPR
- EPSCAS is used in place of MSRDS
- EPSCPID is used in place of PID
- EPSCGS is used in pace of MSRGS <E.HV>
- EPSCLPID is used in pace of LPIDR <E.HV>

This instruction is privileged.

**Corequisite Categories:**
64-Bit

**Special Registers Altered:**
None

---

**Programming Note**

This instruction behaves identically to a `stdx` 
instruction except for using the EPSC register to 
provide the translation context.
Data Cache Block Store by External PID

X-form

```
dcbstep RA,RB
```

Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required, a block containing the byte addressed by EA is in the data cache of any thread, and any locations in the block are considered to be modified there, then those locations are written to main storage. Additional locations in the block may be written to main storage. The block ceases to be considered modified in that data cache.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this thread, and any locations in the block are considered to be modified there, those locations are written to main storage. Additional locations in the block may be written to main storage, and the block ceases to be considered modified in that data cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

The instruction is treated as a Load with respect to translation, memory protection, and is treated as a Write with respect to debug events.

This instruction is privileged.

For dcbstep, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSR[GS]<E.HV>
- EPLCELPI is used in place of LPIDR<E.HV>

Special Registers Altered:
None

Programming Note
This instruction behaves identically to a dcbst instruction except for using the EPLC register to provide the translation context.

---

Data Cache Block Touch by External PID

X-form

```
dcbtep TH,RA,RB
```

Let the effective address (EA) be the sum (RA|0)+(RB).

The dcbtep instruction provides a hint that the program will probably soon load from the block containing the byte addressed by EA. If the Cache Specification category is supported, the nature of the hint is affected by TH values of 0b00000 to 0b00111. Values associated with the Stream category are ignored. See Section 4.3.2 of Book II for more information.

If the block is in a storage location that is Caching Inhibited or Guarded, the hint is ignored.

The only operation that is “caused” by the dcbtep instruction is the providing of the hint. The actions (if any) taken in response to the hint are not considered to be “caused by” or “associated with” the dcbtep instruction (e.g., dcbtep is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by the memory barrier created by a sync instruction.

The dcbtep instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified in the dcbt instruction in Section 4.3.2 of Book II.

The instruction is treated as a Load, except that no interrupt occurs if a protection violation occurs.

The instruction is privileged.

The normal address translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSR[GS]<E.HV>
- EPLCELPI is used in place of LPIDR<E.HV>

Special Registers Altered:
None

Extended Mnemonics:
Extended mnemonics are provided for the Data Cache Block Touch by External PID instruction so that it can...
be coded with the TH value as the last operand for all categories.

Extended: dcbtctep RA,RB,TH
Equivalent to:
dcbtep for TH values of 0b0000 - 0b0111;
other TH values are invalid.
dcbtdsep RA,RB,TH
dcbtep for TH values of 0b0000 or 0b1000 - 0b1010;
other TH values are invalid.

Programming Note
This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Data Cache Block Flush by External PID
X-form

dcbfep RA,RB,L

Let the effective address (EA) be the sum (RA|0)+(RB).

L=0

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data caches of all processors.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data cache of this processor.

L=1 ("dcbf local") [Category: Embedded.Phased-In]

The L=1 form of the dcbfep instruction permits a program to limit the scope of the "flush" operation to the data cache of this processor. If the block containing the byte addressed by EA is in the data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

L = 3 ("dcbf local primary") [Category: Embedded.Phased-In]

The L=3 form of the dcbfep instruction permits a program to limit the scope of the "flush" operation to the primary data cache of this processor. If the block containing the byte addressed by EA is in the primary data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

For the L operand, the value 2 is reserved. The results of executing a dcbfep instruction with L=2 are boundedly undefined.

Engineering Note

dcbfep with an L value of 2 should be treated as if the value were 0.

Extended: Equivalent to:
dcbtep for TH values of 0b0000 - 0b0111;
other TH values are invalid.
dcbtep for TH values of 0b0000 or 0b1000 - 0b1010;
other TH values are invalid.

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programmable Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

Programming Note

This instruction behaves identically to a dcbt instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.
The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

The instruction is treated as a Load with respect to translation, memory protection, and is treated as a Write with respect to debug events.

This instruction is privileged.

The normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSRGS<E.HV>
- EPLCELPID is used in place of LPIDR<E.HV>

Special Registers Altered:
None

Programming Note

This instruction behaves identically to a dcbf instruction except for using the EPLC register to provide the translation context.

Extended Mnemonics:

Extended mnemonics are provided for the Data Cache Block Flush by External PID instruction so that it can be coded with the L value as part of the mnemonic rather than as a numeric operand. These are shown as examples with the instruction. See Section B.2 of Book III-E. The extended mnemonics are shown below.

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>dcbfep RA,RB</td>
<td>dcbfep RA,RB,0</td>
</tr>
<tr>
<td>dcbflep RA,RB</td>
<td>dcbfep RA,RB,1</td>
</tr>
<tr>
<td>dcbflep RA,RB</td>
<td>dcbfep RA,RB,3</td>
</tr>
</tbody>
</table>

Except in the dcbfep instruction description in this section, references to “dcbfep” in Books I-III imply L=0 unless otherwise stated or obvious from context; “dcbflep” is used for L=1 and “dcbflep” is used for L=3.

Programming Note

dcbfep serves as both a basic and an extended mnemonic. The Assembler will recognize a dcbfep mnemonic with three operands as the basic form, and a dcbfep mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.
Data Cache Block Touch for Store by External PID

The `dcbtstep` instruction provides a hint that the program will probably soon store to the block containing the byte addressed by EA. If the Cache Specification category is supported, the nature of the hint is affected by TH values of 0b00000 to 0b00111. Values associated with the Stream category are ignored. See Section 4.3.2 of Book II for more information.

If the block is in a storage location that is Caching Inhibited or Guarded, the hint is ignored.

The only operation that is “caused” by the `dcbtstep` instruction is the providing of the hint. The actions (if any) taken in response to the hint are not considered to be “caused by” or “associated with” the `dcbtstep` instruction (e.g., `dcbtstep` is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by the memory barrier created by a `sync` instruction.

The `dcbtstep` instruction may complete before the operation it causes has been performed.

The instruction is treated as a Store, except that no interrupt occurs if a protection violation occurs.

The instruction is privileged.

The normal address translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- `EPLCEPR` is used in place of `MSRPR`
- `EPLCEAS` is used in place of `MSRDS`
- `EPLCEPID` is used in place of `PID`
- `EPLCEGSS` is used in place of `MSR[GS] <E.HV>`
- `EPLCELPID` is used in place of `LPIDR <E.HV>`

Special Registers Altered:

None

Extended Mnemonics:

Extended mnemonics are provided for the `Data Cache Block Touch for Store by External PID` instruction so that it can be coded with the TH value as the last operand for all categories.

**Extended:**

- `dcbtstep RA,RB,TH`

**Equivalent to:**

- `dcbtstep` for TH values of 0b0000 - 0b0111;
  - other TH values are invalid.

### Programming Note

This instruction behaves identically to a `dcbtst` instruction except for using the EPLC register to provide the translation context, and not supporting the Stream category.

0 & & & & \\
\end{array}

if \ RA = 0 \ then \ b \leftarrow 0 \\
else \ b \leftarrow (RA) \\
EA \leftarrow b + (RB) \\
FRT \leftarrow \text{MEM}(EA,8)

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into FRT.

For \text{lfdepx}, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSR[GS] <E.HV>
- EPLCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

An attempt to execute \text{lfdepx} while MSR\_FP=0 will cause a Floating-Point Unavailable interrupt.

Corequisite Categories: Floating-Point

Special Registers Altered: None

---

Programming Note

This instruction behaves identically to a \text{lfdx} instruction except for using the EPLC register to provide the translation context.

---

Store Floating-Point Double by External Process ID Indexed X-form

\text{stfdepx} \ FRS,RA,RB

\begin{array}{ccc}
31 & FRS & RA & RB & 735 \\
0 & & & & \\
\end{array}

if \ RA = 0 \ then \ b \leftarrow 0 \\
else \ b \leftarrow (RA) \\
EA \leftarrow b + (RB) \\
\text{MEM}(EA,8) \leftarrow (FRS)

Let the effective address (EA) be the sum (RA|0)+(RB). (FRS) is stored into the doubleword in storage addressed by EA.

For \text{stfdepx}, the normal translation mechanism is not used. The contents of the EPSC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPSCEPR is used in place of MSRPR
- EPSCEAS is used in place of MSRDS
- EPSCEPID is used in place of PID
- EPSCEGS is used in place of MSR[GS] <E.HV>
- EPSCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

An attempt to execute \text{stfdepx} while MSR\_FP=0 will cause a Floating-Point Unavailable interrupt.

Corequisite Categories: Floating-Point

Special Registers Altered: None

---

Programming Note

This instruction behaves identically to a \text{stfdx} instruction except for using the EPSC register to provide the translation context.
Vector Load Doubleword into Doubleword by External Process ID Indexed EVX-form

evlddepx RT,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
RT ← MEM(EA,8)

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into RT.

For evlddepx, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPLC_EPR is used in place of MSRPR
- EPLC_EAS is used in place of MSR_DS
- EPLC_EPID is used in place of PID
- EPLC_EGS is used in place of MSR[GS] <E.HV>
- EPLC_ELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

An attempt to execute evlddepx while MSR_SPV=0 will cause an SPE Unavailable interrupt.

Corequisite Categories:
Signal Processing Engine

Special Registers Altered:
None

Programming Note
This instruction behaves identically to a evlddx instruction except for using the EPLC register to provide the translation context.

Vector Store Doubleword into Doubleword by External Process ID Indexed EVX-form

evstddepx RS,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
MEM(EA,8) ← (RS)

Let the effective address (EA) be the sum (RA|0)+(RB). (RS) is stored into the doubleword in storage addressed by EA.

For evstddepx, the normal translation mechanism is not used. The contents of the EPSC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:

- EPSCE_EPR is used in place of MSRPR
- EPSCE_EAS is used in place of MSR_DS

Programming Note
This instruction behaves identically to a evstddx instruction except for using the EPSC register to provide the translation context.
Load Vector by External Process ID
Indexed X-form

Ivepx  VRT,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
VRT ← MEM(EA & 0xFFFF_FFFF_FFFF_FFF0, 16)

Let the effective address (EA) be the sum (RA|0)+(RB). The quadword in storage addressed by the result of EA ANDed with 0xFFFF_FFFF_FFFF_FFF0 is loaded into VRT.

For Ivepx, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:
- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSR[GS] <E.HV>
- EPLCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

An attempt to execute Ivepx while MSR SPV=0 will cause a Vector Unavailable interrupt.

Corequisite Categories:
Vector

Special Registers Altered:
None

Programming Note
This instruction behaves identically to a lvx instruction except for using the EPLC register to provide the translation context.

Load Vector by External Process ID
Indexed LRU X-form

Ivepxl  VRT,RA,RB

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
VRT ← MEM(EA & 0xFFFF_FFFF_FFFF_FFF0, 16)
mark_as_not_likely_to_be_needed_again_anytime_soon(EA)

Let the effective address (EA) be the sum (RA|0)+(RB). The quadword in storage addressed by the result of EA ANDed with 0xFFFF_FFFF_FFFF_FFF0 is loaded into VRT.

Ivepxl provides a hint that the quadword in storage addressed by EA will probably not be needed again by the program in the near future.

For Ivepxl, the normal translation mechanism is not used. The contents of the EPLC register are used to provide the context in which translation occurs. The following substitutions are made for just the translation and access control process:
- EPLCEPR is used in place of MSRPR
- EPLCEAS is used in place of MSRDS
- EPLCEPID is used in place of PID
- EPLCEGS is used in place of MSR[GS] <E.HV>
- EPLCELPID is used in place of LPIDR <E.HV>

This instruction is privileged.

An attempt to execute Ivepxl while MSR SPV=0 will cause a Vector Unavailable interrupt.

Corequisite Categories:
Vector

Special Registers Altered:
None

Programming Note
See the Programming Notes for the lvxl instruction in Section 5.7.2 of Book I.

Programming Note
This instruction behaves identically to a lvxl instruction except for using the EPLC register to provide the translation context.

---

### Programming Note

This instruction behaves identically to a **stvxl** instruction except for using the EPSC register to provide the translation context.
Chapter 6. Storage Control

6.1 Overview

Instruction effective addresses are generated for sequential instruction fetches and for addresses that correspond to a change in program flow (branches, interrupts). Data effective addresses are generated by Load, Store, and Cache Management instructions. TLB Management instructions generate effective addresses to determine the presence of or to invalidate a specific TLB entry associated with that address. For a complete discussion of storage addressing and effective address calculation, see Section 1.10 of Book I.

Portions of the context of an effective address are appended to it to form the virtual address. The context is provided by various registers. The virtual address consists of the Logical Partition ID (LPID) <E.HV>, the Guest State <E.HV>, the address space identifier, the process identifier, and the effective address. The virtual address is translated to a real address by a matching “direct” entry in the Translation Lookaside Buffer (TLB) according to procedures described in Section 6.7.3. The Virtual Page Number (VPN) part of the virtual address is compared to the TLB contents to determine a match. The VPN consists of bits of the virtual address with the exception of the low-order effective address bits that correspond to the byte offset within the page. If the Embedded.Page Table category is supported, a virtual address can be translated by the Page Table pointed to by a matching “indirect” TLB entry as described in Section 6.7.4. As a result of a Page Table translation, a direct TLB entry is created, and this direct TLB entry can be used for subsequent translations. All virtual addresses are translated by the Page Table <E.PT> or the TLB, i.e. unlike the Server environment, there is no real mode. The real address that results from the translation is used to access main storage.

The Translation Lookaside Buffer is the hardware resource that also controls protection and storage control attributes. TLB permission bits control user and supervisor read, write and execute capability. If the Embedded.Hypervisor category is supported, the Virtualization Fault bit permits data accesses to pages to be trapped to the hypervisor, which allows the hypervisor to virtualize data accesses to specific pages, e.g. accesses to memory-mapped I/O. Storage control attributes described in Book II are supported by corresponding TLB bits, as are four optional implementation-dependent user-defined storage control attributes. The organization of the TLB (e.g. associativity, number of entries, number of arrays, etc.) is implementation-dependent. MMU configuration and TLB configuration information in various registers describes this implementation-dependent organization.

Software manages translation directly by installing TLB entries, and indirectly by setting up the page tables, which the TLB will cache. TLB Management instructions are used by software to read, write, search and invalidate TLB contents. MMU Assist Registers (MAS) are used to transfer data to and from the TLB arrays by TLB Management instructions. If the Embedded.Hypervisor category is not supported, TLB Management instructions are privileged instructions.

A different MMU Architecture Version (MAV) is used to indicate that different register layouts and functions are provided. The MMU Architecture Version Number is specified by the read-only MMUCFG register. The Embedded.Hypervisor.LRAT, Embedded TLB Write Conditional, and Embedded.Page Table categories are available only in MMU Architecture Version 2.0.

If the Embedded.Hypervisor category is supported and the Embedded.Hypervisor.LRAT category is not supported, most TLB Management instructions are hypervisor instructions. TLB entries contain real addresses, and, to maintain isolation between partitions, guest operating systems are not given access to real addresses. In this case most TLB Management instructions trap to the hypervisor. The hypervisor can emulate a TLB Management instruction by swapping a Real Page Number for corresponding Logical Page Number (LPN) in the MAS registers or vice versa so that the guest OS only sees LPNs.

However, if the Embedded.Hypervisor.LRAT category is supported, hardware can perform the translation of an LPN into a corresponding RPN. In this case, a TLB Write Entry (tlbwe) instruction can be executed in guest supervisor state. The LPN in the MAS register is translated into a corresponding RPN by a hardware lookup in a Logical to Real Address Translation (LRAT)
array, and the RPN is written to the TLB in place of the LPN when \texttt{tlbwe} is executed in guest supervisor state.

The Embedded.TLB Write Conditional (E.TWC) category provides a TLB write operation that is conditional on a TLB-reservation where the TLB-reservation is previously established by a \texttt{tlbsrx} instruction. The TLB-reservation is cleared by TLB invalidations and TLB writes involving the same virtual page. Thus, without acquiring a software lock, software can use the E.TWC category to write a TLB entry while ensuring that the entry is not a duplicate of an entry created simultaneously by another thread that shares the TLB and is not a stale value for a virtual page that was concurrently invalidated.

Figure 19 gives an overview of address translation if the Embedded.Page Table category is supported. The IND bit in a TLB entry indicates whether the entry is a "direct" entry or "indirect" entry. When a virtual address is translated, the TLB arrays are searched for a matching entry. If there is one and only one matching direct entry, that entry is used to translate the VA. If there is no matching direct TLB entry, but there is one and only one matching indirect entry, the indirect entry is used to access a Page Table Entry (PTE). If the PTE is a valid entry (V bit = 1), the PTE is used to translate the address and a "direct" entry is written to the TLB. If the Embedded.Page Table and Embedded.Hypervisor categories are both supported, the Embedded.Hypervisor.LRAT category is supported. In this case if the TGS bit of the indirect TLB entry is 1, the RPN from the PTE is treated as a Logical Page Number (LPN) and translated by the LRAT into an RPN. If the Embedded.Page Table is supported but the Embedded.Hypervisor category is not supported, supervisor software can create direct and indirect TLB entries and control the Page Table Entries. If both categories are supported, guest supervisor software can still create direct and indirect TLB entries and control the Page Table Entries if guest execution of \textit{TLB Management} instructions is enabled. However, depending on various factors such as the number of available LRAT entries, performance may be better if guest virtual addresses are translated by a Page Table that is managed by hypervisor software.

![Figure 19. Address translation with page table](image)

**Address Size Overview**

- Real address space size is $2^m$ bytes, $m\leq64$; see Note 1.
- In MMU Architecture Version 1.0, real page sizes are $4^p$ KB where $0\leq p \leq 15$ (i.e. 1 KB, 4 KB, 16 KB, 64 KB, 256 KB, 1 MB, 4 MB, 16 MB, 64 MB, 256 MB, 1 GB, 4 GB, 16 GB, 64 GB, 256 GB, 1 TB); see Note 2. In MMU Architecture Version 2.0, real page sizes are $2^p$ KB where $0\leq p \leq 31$ (i.e. 1 KB, 2 KB, 4 KB, 8 KB, 16 KB, 32 KB, 64 KB, 128 KB, 256 KB, 512 KB, 1 MB, 2 MB, 4 MB, 8 MB, 16 MB, 32 MB, 64 MB, 128 MB, 256 MB, 512 MB, 1 GB, 2 GB, 4 GB, 8 GB, 16 GB, 32 GB, 64 GB, 128 GB, 256 GB, 512 GB, 1 TB, 2 TB); see Note 2. However, real pages sizes supported by a Page Table are limited to values of $p$ where $2\leq p \leq 15$.
- Effective address space size is $2^{64}$ bytes in 64-bit implementations and $2^{32}$ bytes in 32-bit implementations.
- The virtual address space size depends on the implementation.
6.2 Storage Exceptions

A storage exception results when the sequential execution model requires that a storage access be performed but the access is not permitted (e.g., is not permitted by the storage protection mechanism), the access cannot be performed because the effective address cannot be translated to a real address, or the access matches some tracking mechanism criteria (e.g., Data Address Compare Debug Interrupt).

In certain cases a storage exception may result in the “restart” of (re-execution of at least part of) a Load or Store instruction. See Section 2.1 of Book II and Section 7.7 on page 1186 in this Book.

6.3 Instruction Fetch

For an instruction fetch, MSR\textsubscript{IS} is appended to the effective address as part of the virtual address. The Address Translation mechanism is described in Section 6.7.2, Section 6.7.3, and, if the Embedded.Page Table category is supported, Section 6.7.4.

6.3.1 Implicit Branch

Explicitly altering certain MSR bits (using \texttt{mtmsr}), or explicitly altering TLB entries, certain System Registers and possibly other implementation-dependent registers, may have the side effect of changing the addresses, effective or real, from which the current instruction stream is being fetched. This side effect is called an implicit branch. For example, an \texttt{mtmsr} instruction that changes the value of MSR\textsubscript{CM} may change the real address from which the current instruction stream is being fetched. The MSR bits and System Registers (excluding implementation-dependent registers) for which alteration can cause an implicit branch are indicated as such in Chapter 12, “Synchronization Requirements for Context Alterations” on page 1235.

Implicit branches are not supported by the Power ISA. If an implicit branch occurs, the results are boundedly undefined.
6.3.2 Address Wrapping Combined with Changing MSR Bit CM

If the current instruction is at effective address $2^{32}$.4 and is an \textit{mtsr} instruction that changes the contents of MSR$_{CM}$, the effective address of the next sequential instruction is undefined.

\begin{center}
\textbf{Programming Note}
\end{center}

In the case described in the preceding paragraph, if an interrupt occurs before the next sequential instruction is executed, the contents of SRR0, CSR0, or MCSRR0, as appropriate to the interrupt, are undefined if the Embedded.Hypervisor category is not supported or the interrupt is directed to the guest state. If the Embedded.Hypervisor category is supported and the interrupt is directed to the hypervisor state, the contents of GSRR0 are undefined.

6.4 Data Access

For a normal Load or Store instruction, MSR$_{DS}$ is appended to the effective address as part of the virtual address. The Address Translation mechanism is described in Section 6.7.2, Section 6.7.3, and, if the Embedded.Page Table category is supported, Section 6.7.4. The Embedded.External PID category must be supported. The effective address for an External Process ID Load or Store instruction data access is processed under control of the EPLC or EPSC, respectively. See Section 5.3.7.1 and Section 5.3.7.2.

6.5 Performing Operations Out-of-Order

An operation is said to be performed “in-order” if, at the time that it is performed, it is known to be required by the sequential execution model. An operation is said to be performed “out-of-order” if, at the time that it is performed, it is not known to be required by the sequential execution model.

Operations are performed out-of-order on the expectation that the results will be needed by an instruction that will be required by the sequential execution model. Whether the results are really needed is contingent on everything that might divert the control flow away from the instruction, such as Branch, Trap, System Call, and Return From Interrupt instructions, and interrupts, and on everything that might change the context in which the instruction is executed.

Typically, operations are performed out-of-order when resources are available that would otherwise be idle, so the operation incurs little or no cost. If subsequent events such as branches or interrupts indicate that the operation would not have been performed in the sequential execution model, any results of the operation are abandoned (except as described below).

In the remainder of this section, including its subsections, “Load instruction” includes the Cache Management and other instructions that are stated in the instruction descriptions to be “treated as a Load”, and similarly for “Store instruction”.

A data access that is performed out-of-order may correspond to an arbitrary Load or Store instruction (e.g., a Load or Store instruction that is not in the instruction stream being executed). Similarly, an instruction fetch that is performed out-of-order may be for an arbitrary instruction (e.g., the aligned word at an arbitrary location in instruction storage).

Most operations can be performed out-of-order, as long as the machine appears to follow the sequential execution model. Certain out-of-order operations are restricted, as follows.

\begin{itemize}
  \item Stores
    Stores are not performed out-of-order (even if the Store instructions that caused them were executed out-of-order).
  \item Accessing Guarded Storage
    The restrictions for this case are given in Section 6.8.1.1.
\end{itemize}

The only permitted side effects of performing an operation out-of-order are the following.

\begin{itemize}
  \item A Machine Check that could be caused by in-order execution may occur out-of-order except that, if category E.HV is supported and the Machine Check is the result of multiple TLB entries that translate the same VA, the Machine Check interrupt must occur in the context in which it was caused. Also, if category E.HV is supported, a Machine Check interrupt resulting from the following situations must be precise.
    \begin{itemize}
      \item Execution of an External Process ID instruction that has an operand that can be translated by multiple TLB entries.
      \item Execution of a \textit{tlbivax} instruction that isn't a TLB invalidate all and there are multiple entries in a single thread's TLB array(s) that match the complete VPN.
      \item Execution of a \textit{tlbli} instruction with T=3 and there are multiple entries in the TLB array(s) that match the complete VPN.
      \item Execution of a \textit{tlbsx} or \textit{tlbsrx} instruction and there are multiple matching TLB entries.
    \end{itemize}
  \item Non-Guarded storage locations that could be fetched into a cache by in-order fetching or execution of an arbitrary instruction may be fetched out-of-order into that cache.
\end{itemize}
6.6 Invalid Real Address

A storage access (including an access that is performed out-of-order; see Section 6.5) may cause a Machine Check if the accessed storage location contains an uncorrectable error or does not exist. See Section 7.6.3 on page 1165.

6.7 Storage Control

This section describes the address translation facility, access control, and storage control attributes.

Demand-paged virtual memory is supported, as well as a variety of other management schemes that depend on precise control of effective-to-real address translation and flexible memory protection. Translation misses and protection faults cause precise exceptions. Sufficient information is available to correct the fault and restart the faulting instruction.

The effective address space is divided into pages. The page represents the granularity of effective address translation, access control, and storage control attributes. In MMU Architecture Version 1.0, up to sixteen page sizes (1KB, 4KB, 16KB, 64KB, 256KB, 1MB, 4MB, 16MB, 64MB, 256MB, 1GB, 4GB, 16GB, 64GB, 256GB, 1TB) may be simultaneously supported. In MMU Architecture Version 2.0, up to 32 page sizes (1KB, 2 KB, 4 KB, 8 KB, 16KB, 32KB, 64KB, 128KB, 256KB, 512KB, 1MB, 2MB, 4MB, 8MB, 16MB, 32MB, 64MB, 128MB, 256MB, 512MB, 1GB, 2GB, 4GB, 8GB, 16GB, 32GB, 64GB, 128GB, 256GB, 512GB, 1TB, 2TB) may be simultaneously supported. In order for an effective to real translation to exist, a valid entry for the page containing the effective address must be in the Translation Lookaside Buffer (TLB). Addresses for which no TLB entry exists cause TLB Miss exceptions.

6.7.1 Translation Lookaside Buffer

The Translation Lookaside Buffer (TLB) is the hardware resource that controls translation, protection, and storage control attributes. The organization of the TLB (e.g. associativity, number of entries, number of arrays, etc.) is implementation-dependent. Thus, the software for updating the TLB is also implementation-dependent. However, MMU configuration and TLB configuration information is provided such that software written to handle various TLB organizations could potentially run on multiple MMU implementations. A unified TLB organization (one to four TLB arrays, called TLB0, TLB1, TLB2 and TLB3, where each contains translations for both instructions and data) is assumed in the following description. For details on how to synchronize TLB updates with instruction execution see Section 6.11.4.3 and Chapter 12.

Maintenance of TLB entries is under software control, except that if the Embedded.Page Table category is supported, hardware will write TLB entries for translations performed via the Page Table. System software determines TLB entry replacement strategy and the format and use of any page state information. If a TLB provides Next Victim (NV) information, software can optionally use NV to choose a TLB entry to be replaced. See Section 6.11.4.7. Some implementations allow software to specify that a hardware generated hash and hardware replacement algorithm should be used to select the entry. See Section 6.11.4.7. The TLB entry contains all the information required to identify the page, to specify the translation, to specify access controls, and to specify the storage control attributes.

A TLB entry is written by copying information from MAS registers, using a tlbwe instruction (see page 1141). A TLB entry is read by copying information to MAS registers, using a tlbre instruction (see page 1139). Software can also search for specific TLB entries using the tlbsx instruction (see page 1136) and, if the Embedded.TLB Write Conditional category is supported, tlbxsx. (see page 1138).

Each TLB entry describes a page. Fields in the TLB entry fall into five categories:

- Page identification fields (information required to identify the page to the hardware translation mechanism).
- Address translation fields
- Access control fields
- Storage control attribute fields
- TLB management field

While the fields in the TLB entry are required, unless they are identified as part of a category that is not supported, no particular TLB entry format is formally specified. The tlbre and tlbwe instructions provide the ability to read or write individual entries. Below are shown the field definitions for the TLB entry. Some fields that are used only for indirect TLB entries can be overlaid with fields that are used only for direct TLB entries. Such overlap is implementation-dependent and an example is shown in Figure 20 on page 1081.
### Page Identification Fields for direct and indirect entries

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>EPN</td>
<td>Effective Page Number (up to 54 bits)</td>
</tr>
</tbody>
</table>

Bits 0:\(n\)–1 of the EPN field are compared to bits 0:\(n\)–1 of the effective address (EA) of the storage access (where \(n=64–\log_2(\text{page size in bytes})\) and \text{page size} is specified by the SIZE field of the TLB entry). See Table 2 and Table 3.

**Note:** Bits X:Y of the EPN field are implemented, where X=0 (64-bit implementation) or X=32 (32-bit implementation), and Y ≤ 53. \(Y = p - 1\) where \(p = 64–\log_2(\text{smallest page size in bytes})\) and \text{smallest page size} is the smallest page size supported by the implementation as specified by TLB array’s TLBnCFG or TLBnPS. The number of bits implemented for EPN is not required to be the same number of bits as are implemented for RPN. Implemented bits that represent offsets within a page are ignored for address comparisons performed for translation, invalidation, and searches and software should set these bits to zero. Unimplemented EPN bits are treated as if they contain 0s.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TS</td>
<td>Translation Address Space</td>
</tr>
</tbody>
</table>

This bit indicates the address space this TLB entry is associated with. For instruction storage accesses, MSRIS must match the value of TS in the TLB entry to provide the translation. Likewise, for data storage accesses, MSRDS must match the value of TS in the TLB entry. For the \texttt{tlbsrx. <E.TWC>} instruction, MAS1TS provides the address space specification that must match the value of TS. For the \texttt{tlbsx} instruction, MAS6SAS provides the address space specification that must match the value of TS. For the instructions \texttt{tiblix} with T=3 and \texttt{tibivax} with EA61=0, MAS6SAS provides the address space specification that is compared to the value of TS.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SIZE</td>
<td>Page Size</td>
</tr>
</tbody>
</table>

For direct TLB entries, the SIZE field specifies the size of the virtual page associated with the TLB entry. For indirect TLB entries, the SIZE field specifies the maximum amount of virtual storage that can be mapped by the page table to which the indirect TLB entry points. The following applies in both cases:

- For MAV = 1.0, \(4^{\text{SIZEKB}}, 0 ≤ \text{SIZE} ≤ 15\). See Table 2. For TLB arrays that contain fixed-size TLB entries, this field is treated as reserved for \text{tlbwe} and \text{tlbre} instructions and is treated as a fixed value for translations. For variable page size TLB arrays, this field must be a value between TLBnCFG\_MINSIZE and TLBnCFG\_MAXSIZE.

- For MAV = 2.0, \(2^{\text{SIZEKB}}, 0 ≤ \text{SIZE} ≤ 31\). See Table 3. This field must be one of the page sizes specified by the corresponding TLBnPS register.

Implementations may support any one or more of the page sizes described above.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TID</td>
<td>Translation ID (implementation-dependent size)</td>
</tr>
</tbody>
</table>

Field used to identify a shared page (TID=0) or the owner’s process ID of a private page (TID≠0). See Section 6.7.2.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TLPID</td>
<td>Translation Logical Partition ID &lt;E.HV&gt;</td>
</tr>
</tbody>
</table>

This field identifies a partition. The Translation Logical Partition ID is compared with LPIDR contents during translation. This allows for an efficient change of address space when a transition between partitions occurs. This number of bits in this field is an implementation-dependent number \(n\), where 1 ≤ \(n\) ≤ 12. See Section 6.7.2.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>TGS</td>
<td>Translation Guest State &lt;E.HV&gt;</td>
</tr>
</tbody>
</table>

This 1-bit field indicates whether this TLB entry is valid for the guest space or for the hypervisor space. The Translation Guest Space field is compared with the MSR\_GS bit during translation. This allows for an efficient change of address space when a transition from guest state to hypervisor state occurs. See Section 6.7.2.

- 0 Hypervisor space
- 1 Guest space
This bit indicates whether that this TLB entry is valid and may be used for translation. The Valid bit for a given entry can be set or cleared with a *tlbwe* instruction; alternatively, the Valid bit for an entry may be cleared by a *tlbilx* or *tlbivax* instruction or by a MMUCSR0 TLB invalidate all.

**IND Indirect <E.PT>**

This bit distinguishes between an indirect TLB entry that points to a Page Table (IND=1) and a direct TLB entry that can be used directly to translate a virtual address (IND=0). If a TLB array does not support this bit (TLBnCFGIND = 0), the implied IND value is 0. For the *tlbsx* instruction, MAS6SIND provides the direct/indirect specification that must match the value of IND. For the instructions *tlbilx* with T=3 and *tlbivax* with EA61=0, MAS6SIND provides the direct/indirect specification that is compared to the value of IND. See Section 6.7.4.

**Page Identification Field for indirect entry**

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SPSIZE</td>
<td>Sub-Page Size (IND=1) &lt;E.PT&gt;</td>
</tr>
<tr>
<td></td>
<td>SPSIZE is a 5-bit field that specifies the minimum page size that can be specified by each Page Table Entry in the Page Table that is pointed to by the indirect TLB entry. This minimum page size is $2^{SPSIZE}$ KB and must be at least 4 KB. Thus SPSIZE must be at least 2. Valid values are specified by EPTCFG$_{SPS2 SPS1 SPS0}$. See Section 6.7.4.</td>
</tr>
</tbody>
</table>

**Translation Field**

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>RPN</td>
<td><strong>Real Page Number</strong> (up to 54 bits)</td>
</tr>
<tr>
<td></td>
<td>For a direct TLB entry, bits $0:n-1$ of the RPN field are used to replace bits $0:n-1$ of the effective address to produce the real address for the storage access (where $n=$64−log$_2$(<em>page size in bytes</em>) and <em>page size</em> is specified by the SIZE field of the TLB entry). See Section 6.7.3 for a requirement on unused low-order RPN bits (i.e. bits $n:53$) being 0. For an indirect TLB entry, bits $0:m-1$ of the RPN field followed by 64- m 0s are the real address of the page table pointed to the indirect TLB entry, where $m=$ 61 − (SIZE − SPSIZE). RPN bits m:53 must be zero. See Section 6.7.4.</td>
</tr>
</tbody>
</table>

**Note:** Bits X:Y of the RPN field are implemented, where $X \geq 0$ and $Y \leq 53$. $X = 64 - MMUCFG_{RASIZE}$. $Y$ is the larger of the following applicable values:

- $p-1$ where $p=64-\log_2(\text{smallest page size in bytes})$ and *smallest page size* is the smallest page size supported by the implementation as specified by TLB array's TLBnCFG or TLBnPS.
- 52 if the Embedded.Page Table category is supported and a page table size of 2 KB is supported (EPTCFG$_{SPS2} = EPTCFG_{SPS1} = 8$ for some value of $n$).

The number of bits implemented for EPN is not required to be the same number of bits as are implemented for RPN. Unimplemented RPN bits are treated as if they contain 0s.

**Storage Control Bits** (see Section 6.8.3 on page 1097)

<table>
<thead>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>W</td>
<td><strong>Write-Through Required</strong></td>
</tr>
<tr>
<td></td>
<td>This bit indicates whether the page is Write-Through Required. See Section 1.6.1 of Book II.</td>
</tr>
<tr>
<td>0</td>
<td>This page is not Write-Through Required storage.</td>
</tr>
<tr>
<td>1</td>
<td>This page is Write-Through Required storage.</td>
</tr>
</tbody>
</table>

| I           | **Caching Inhibited**                                                       |
|             | This bit indicates whether the page is Caching Inhibited. See Section 1.6.2 of Book II. |
| 0           | This page is not Caching Inhibited storage.                                 |
| 1           | This page is Caching Inhibited storage.                                     |
M  Memory Coherence Required
   This bit indicates whether the page is Memory Coherence Required. See Section 1.6.3 of Book II.
   0  This page is not Memory Coherence Required storage.
   1  This page is Memory Coherence Required storage.

G  Guarded
   This bit indicates whether the page is Guarded. See Section 1.6.4 of Book II and Section 6.8.1.
   0  This page is not Guarded storage.
   1  This page is Guarded storage.

E  Endian Mode
   This bit indicates whether the page is accessed in Little-Endian or Big-Endian byte order. See Section 1.10.1 of Book I and Section 1.6.5 of Book II.
   0  The page is accessed in Big-Endian byte order.
   1  The page is accessed in Little-Endian byte order.

U0:U3  User-Definable Storage Control Attributes
       See Section 6.8.2.
       Specifies implementation-dependent and system-dependent storage control attributes for the page associated with the TLB entry. The existence of these bits is implementation-dependent.

VLE  Variable Length Encoding <E>VLE>
   This bit specifies whether a page which contains instructions is to be decoded as VLE instructions (see Chapter 1 of Book VLE). See Section 6.8.3 and Chapter 1 of Book VLE.
   0  Instructions fetched from the page are decoded and executed as non-VLE instructions.
   1  Instructions fetched from the page are decoded and executed as VLE instructions.

ACM  Alternate Coherency Mode
   This bit allows an implementation to employ more than a single coherency method. This allows participation in multiple coherency protocols. If the M attribute (Memory Coherence Required) is not set for a page (M=0), the page has no coherency associated with it and the ACM attribute is ignored. If the M attribute is set to 1 for a page (M=1), the ACM attribute is used to determine the coherency domain (or protocol) used. The coherency method used in Alternate Coherency Mode is implementation-dependent.

Access Control Fields for direct TLB entry

<td></td>
</tr>
</tbody>
</table>
There are two separate address spaces supported. MSR\textsubscript{IS} and MSR\textsubscript{DS} are used to indicate the address space used for instruction and data accesses respectively. MSR\textsubscript{IS} and MSR\textsubscript{DS} can be set independently to access address space 0 or address space 1. TLB entries have a corresponding TS bit which is compared either to MSR\textsubscript{IS} or MSR\textsubscript{DS} for instruction and data accesses respectively to determine if the TLB entry is a match.

If the Embedded.Hypervisor category is supported, the above two address spaces exist for each logical parti-
tion and for both the guest and non-guest states within each logical partition. The Logical Partition ID Register identifies the partition and a field in the TLB entry (TLPID) specifies which partition that TLB entry is associated with. The Guest State (GS) bit in the Machine State Register identifies the guest state or non-guest state and a bit in the TLB entry (TGS) specifies which of these states that TLB entry is associated with.

Load, Store, Cache Management, and Branch instructions and next-sequential-instruction fetches produce a 64-bit effective address. A one-bit address space identifier and a process identifier are prepended to the effective address to form the virtual address. If the Embedded Hypervisor category is supported, this address is also prepended by a Logical Partition ID and Guest State bit. The Logical Partition ID is provided by the contents of LPIDR and the Guest State bit is provided by the MSRGS. For instruction fetches, the address space identifier is provided by MSRIS and the process identifier is provided by the contents of the Process ID Register. For data storage accesses, the address space identifier is provided by the MSRDS and the process identifier is provided by the contents of the Process ID Register.

Load, Store, Cache Management, and Branch instructions and next-sequential-instruction fetches produce a 64-bit effective address. A one-bit address space identifier and a process identifier are prepended to the effective address to form the virtual address. If the Embedded Hypervisor category is supported, this address is also prepended by a Logical Partition ID and Guest State bit. The Logical Partition ID is provided by the contents of LPIDR and the Guest State bit is provided by the MSRGS. For instruction fetches, the address space identifier is provided by MSRIS and the process identifier is provided by the contents of the Process ID Register. For data storage accesses, the address space identifier is provided by the MSRDS and the process identifier is provided by the contents of the Process ID Register.

Figure 21. Effective-to-Virtual-to-Real TLB Address Translation Flow

6.7.3 TLB Address Translation

A program references memory by using the effective address computed by the hardware when it executes a Load, Store, Cache Management, or Branch instruction, and when it fetches the next instruction. A virtual address is formed from the effective address as described in Section 6.7.2 and the virtual address is translated to a real address according to the procedures described in this section. The storage subsystem uses the real address for the access. All storage access effective addresses are compared to the Translation Address Space bit (TS), the Translation ID field (TID), and the value in the Effective Page Number field (EPN), respectively, of each TLB entry. If the Embedded Hypervisor category is supported, the Logical Partition ID and the Guest State bit are also compared to the Translation Logical Partition ID (TLPID) and Translation Guest State (TGS) of each TLB entry. Figure 22 illustrates the criteria for a virtual address to match a specific TLB entry for a direct TLB entry (IND = 0). See Section 6.7.4 for details on Page Table translation using an indirect TLB entry. The virtual address of a storage access matches a direct TLB entry if the first four following conditions are true, and, additionally, if the Embedded Page Table category is supported, the fifth condition is true, and, addi-
tionally, if the Embedded.Hypervisor category is supported, the last two conditions are true.

- The Valid bit of the TLB entry is 1.
- The value of the address specifier for the storage access (MSRIS for instruction fetches, MSRDS for data storage accesses) is equal to the value in the TS bit of the TLB entry.
- The value of the process identifier in the PID register is equal to the value in the TID field of the TLB entry or the value of the PID field of the TLB entry is equal to 0.
- The contents of bits 0:n-1 of the effective address of the storage access are equal to the value of bits 0:n-1 of the EPN field of the TLB entry (where n=64-\log_2(\text{page size in bytes}) and \text{page size} is specified by the value of the SIZE field of the TLB entry). See Table 2 and Table 3.
- One of the following conditions is true.
  - The TLB array supports the IND bit (TLBnCFGIND = 1) and the IND bit of the TLB entry is equal to 0.
  - The TLB array does not support the IND bit (TLBnCFGIND = 0).
  - Either the value of the logical partition identifier in LPIDR is equal to the value of the TLPID field of the TLB entry, or the value of the TLPID field of the TLB entry is equal to 0.
  - The value of the guest state bit (MSRGs) is equal to the value of the TGS bit of the TLB entry.

### Programming Note

An implementation need not support all page sizes.

If the virtual address of the storage access matches a TLB entry in accordance with the selection criteria specified in the preceding paragraph, the value of the Real Page Number field (RPN) of the matching TLB entry provides the real page number portion of the real address. Let \( n = 64 - \log_2(\text{page size in bytes}) \) where \text{page size} is specified by the SIZE field of the TLB entry. Bits \( n:63 \) of the effective address are appended to bits 0:n-1 of the 54-bit RPN field of the matching TLB entry to produce the 64-bit real address (i.e. \( \text{RA} = \text{RPN}_{n-1:n} \parallel \text{EA}_{n:63} \)) that is presented to main storage to perform the storage access. The page size is determined by the value of the SIZE field of the matching TLB entry. See Table 4 and Table 5. Depending on the page size, certain RPN bits of the matching TLB entry must be zero as shown in Table 4 and Table 5. Otherwise, it is implementation-dependent whether the
address translation is performed as if these RPN bits are 0 or as if the corresponding RA bits are undefined values, or either an Instruction Storage exception (for an instruction fetch) or Data Storage exception (for a data access) occurs. If the specified page size is not supported by the implementation's TLB array, it is implementation-dependent whether the address translation is performed as if the page size was a smaller size or either an Instruction Storage exception (for an instruction fetch) or Data Storage exception (for a data access) occurs.

A TLB Miss exception occurs if there is no valid matching direct entry in the TLB for the page specified by the virtual address (Instruction or Data TLB Error interrupt) and, if the Embedded.Page Table category is supported, there is no matching indirect entry (see Section 6.7.4). A TLB Miss exception for an instruction fetch will result in an Instruction TLB Miss exception type Instruction TLB Error interrupt. A TLB Miss exception for a data storage access will result in a Data TLB Miss exception type Data TLB Error interrupt. Although the possibility exists to place multiple direct and/or multiple indirect entries into the TLB that match a specific virtual address, assuming a set-associative or fully-associative organization, doing so is a programming error. Either one of the matching entries is used or a Machine Check exception occurs if there are multiple matching direct entries or multiple matching indirect entries for an instruction or data access.

The rest of the matching TLB entry provides the access control bits (UX, SX, UW, SW, UR, SR, VF), and stor-
age control attributes (ACM [implementation-dependent], VLE <VLE>, U0, U1, U2, U3, W, I, M, G, E) for the storage access. The access control bits and storage control attribute bits specify whether or not the access is allowed and how the access is to be performed. See Sections 6.7.6 and 6.11.4.

Figure 22. Address Translation: Virtual Address to direct TLB Entry Match Process

6.7.4 Page Table Address Translation [Category: Embedded.Page Table]

A hardware Page Table is a variable-sized data structure that specifies the mapping between virtual page numbers and real page numbers. There can be many hardware Page Tables. Each Page Table is defined by an indirect TLB entry. An indirect TLB entry is an entry that has its IND bit equal to 1.

An indirect TLB entry matches the virtual address if all fields match per Section 6.7.4 except for the IND bit and the IND bit of the TLB entry is 1. If there is no matching direct TLB entry, but there is one and only one matching indirect entry, the indirect entry is used to access a Page Table Entry (PTE) if the VF bit of the indirect TLB entry is 0. If the VF bit of this indirect TLB entry is 1, a Virtualization Fault exception occurs. If the PTE is a valid entry (V bit = 1), the PTE is used to translate the address. The PTE includes the abbreviated RPN (ARPN), page size (PS), storage control (WIMGE), implementation-dependent bits, and storage access control bits (BAPR,C) that are used for the access. If the Embedded.Page Table and Embedded.Hypervisor categories are both supported, the Embedded.Hypervisor.LRAT category is supported. In this case, the RPN from the PTE is treated as a Logical Page Number (LPN) and the LPN is translated by the LRAT into an RPN. See Section 6.9. If there is more than one matching direct TLB entry or more than one matching indirect TLB entry, any one of the duplicate entries may be used or Machine Check exception may occur.

See Section 6.7.5 for the rules that software must follow when updating the Page Table.
Even when the Embedded Hypervisor category is supported, a Page Table can optionally be treated as a guest supervisor resource due to the LRAT.

If the Page Table is treated as a hypervisor resource, the Page Table must be placed in storage to which only the hypervisor has access. Moreover, the contents of the Page Table must be such that non-hypervisor software cannot modify storage that contains hypervisor programs or data. An LRAT identity mapping (LPN=RPN) can be used when the Page Tables are treated as hypervisor resources, especially if only one LRAT entry is provided. If the LRAT identity mapping converts LPNs into RPNs that extend beyond the memory given to the partition, the Page Table Entries still provide the hypervisor with a mechanism to limit a guest's accesses to memory assigned to the partition, assuming guest execution of TLB Management instructions is disabled.

If storage accesses are to scattered virtual pages, an Embedded Page Table could be sparsely used, and, in the worst case, there could be only one valid PTE in the Page Table. In this case it would be more efficient for software to directly load TLB entries rather than have both an indirect TLBE and a direct TLBE, which is loaded from the Page Table.
Figure 23. Page Table Translation

Logical Address translation performed if Category E.HV is supported and the TGS bit of the associated indirect TLB entry is 1.
Figure 23 depicts the Page Table translation for a matching indirect TLB entry (TLBE). The Page Table Entry that is used to translate the Effective Address is selected by a real address formed from some combination of RPN bits from the TLBE and some EA bits. The low-order m bits of the RPN field in the indirect TLB entry must be zeros, where m is \((\text{SIZE} - \text{SPSIZE}) - 7\).

SIZE minus SPSIZE must be greater than 7 (corresponding to a page table size of at least 2 KB; see below under “Page Table Size and Alignment”). The SIZE and SPSIZE fields of the TLBE determine which bits of the RPN and EA are used in the following manner.

1. EA\(_{23:51}\) are shifted right q bits, according to a decode of SPSIZE, to produce a 29-bit result S. The value of q is \((\text{SPSIZE} - 2)\). Bits shifted out of the rightmost bit position are lost.

2. A 21-bit EA mask is formed based on a decode of SIZE and SPSIZE. The EA mask is \((29 - (\text{SIZE} - \text{SPSIZE}))_0 || (\text{SIZE} - \text{SPSIZE})_{-81}\).

3. The EA mask from step 2 is ANDed with the high-order 21 bits of the shifted EA result \(S_{0:20}\) from step 1 to form a 21-bit result.

4. RPN\(_{22:52}\) from the indirect TLB entry is ORed with the 21-bit result from step 3 to form a 21-bit result R.

5. The real address of the PTE is formed as follows:
   \[
   \text{RA} = \text{TLBERPN}_{0:31} || R || S_{21:28} || 0b000
   \]

The doubleword addressed by the real address result from step 5 is the PTE used to translate the EA if the PTE is valid (Valid bit = 1). If the PTE is valid, PTE\(_{PS}\) must be greater than or equal to the SPSIZE of the associated indirect TLB entry and must be less than or equal to the SIZE of the associated indirect TLB entry. The real address (RA) result is formed by concatenating 0x000 with the ARPN\(_{0:31-p}\) from the PTE and with the low-order p bits of EA, where p is equal to \(\log_2(\text{page size specified by PTE}_{PS})\).

\[
\text{RA} = 0x000 || \text{ARPN}_{0:51-p} || \text{EA}_{64-p:63}
\]

However, if an implementation supports a real address with only r bits, \(r<52\), and either the Embedded.Hypervisor category is not supported or the TGS bit of the corresponding indirect TLB entry is 0, the high-order 52-r bits of PTE\(_{ARP}\) are ignored and treated as 0s. If the Embedded.Hypervisor category is supported, an implementation supports a logical address with only q bits, \(q<52\), and the TGS bit of the corresponding indirect TLB entry is 1, the high-order 52-q bits of PTE\(_{ARP}\) are ignored and treated as 0s.

If the Embedded.Hypervisor.LRAT category is supported and the TGS bit of the associated indirect TLB entry is 1, the RA formed from the PTE is treated as a logical real address and translated by the LRAT. If there is no matching entry in the LRAT, an LRAT Miss exception occurs. See Section 6.9. If an LRAT Error interrupt results from this exception, ESR\(_PT\) is set to 1.

If the Page Table Entry that is accessed is invalid (Valid bit = 0), a Page Table Fault exception occurs. An Execute, Read, or Write Access Control exception occurs if a valid PTE is found but the access is not allowed by the access control mechanism. These exceptions are types of Instruction Storage exception or Data Storage exception, depending on whether the effective address is for an instruction fetch or for a data access. See Section 7.6.4 and Section 7.6.5 for additional information about these and other interrupt types. For either of these interrupts caused by a Page Table Fault exception or Execute, Read, or Write Access Control exception due to PTE permissions, ESR\(_PT\) or GESR\(_PT\) is set to 1 (GESR\(_PT\) if the Embedded.Hypervisor LRAT category is supported and the interrupt is directed to the guest. Otherwise, ESR\(_PT\)).
Chapter 6. Storage Control

Version 2.07

1089

Storage Control Attributes for the Page Table

A Page Table must be located in storage that is Big-Endian, Memory Coherence Required, not Caching Inhibited and not Guarded. If the translation of a virtual address matches an indirect TLB entry that has its storage control attribute E bit equal to 1, M bit equal to 0, I bit equal to 1, or G bit = 1, it is implementation-dependent whether the translation is performed as if valid values were substituted for the invalid values or as if the entry doesn’t match, or either an Instruction Storage exception (for an instruction fetch) or Data Storage exception (for a data access) occurs. The Page Table is allowed to be located in storage that is Write Through Required or Not Write Through Required. However, the same W value must be used for a single thread’s indirect and direct TLB entries that map the same PTE. The Implementations may require specific values for ACM and U0:U3.

Ordering of Implicit Accesses to the Page Table

The definition of “performed” given in Books II and III-E applies also to the implicit accesses to the Page Table by the thread in performing address translation. Accesses for performing address translation are considered to be loads in this respect. These implicit accesses are ordered by the sync instruction with L=0 as described below.

The Synchronize instruction is described in Section 4.4.3 of Book II, but only at the level required by an application programmer (sync with L=0 or L=1). This section describes properties of the instruction that are relevant only to operating system and hypervisor software programmers. The sync instruction with L=0 (sync) has the following additional properties.

- The sync instruction provides an ordering function for all stores to the Page Table caused by Store instructions preceding the sync instruction with respect to lookups of the Page Table that are performed, by the thread executing the sync instruction, after the sync instruction completes. Executing a sync instruction ensures that all such stores will be performed, with respect to the thread executing the sync instruction, before any implicit accesses to the affected Page Table Entries, by such Page Table lookups, are performed with respect to that thread.

- In conjunction with the tlbivax and tlbsync instructions, the sync instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the tlbipvax instruction description on page 1141.

Page Table Entry

Each Page Table Entry (PTE) maps a VPN to an RPN. If the corresponding indirect TLB entry has an LPID <E.HV> or PID value of zero, multiple VPNs are mapped by a single PTE in a Page Table pointed to by

Programming Note

For instructions following a sync instruction, the memory barrier need not order implicit storage accesses for purposes of address translation.

Storage Control Attributes for the Page Table

A Page Table must be located in storage that is Big-Endian, Memory Coherence Required, not Caching Inhibited and not Guarded. If the translation of a virtual address matches an indirect TLB entry that has its storage control attribute E bit equal to 1, M bit equal to 0, I bit equal to 1, or G bit = 1, it is implementation-dependent whether the translation is performed as if valid values were substituted for the invalid values or as if the entry doesn’t match, or either an Instruction Storage exception (for an instruction fetch) or Data Storage exception (for a data access) occurs. The Page Table is allowed to be located in storage that is Write Through Required or Not Write Through Required. However, the same W value must be used for a single thread’s indirect and direct TLB entries that map the same PTE. The Implementations may require specific values for ACM and U0:U3.

Ordering of Implicit Accesses to the Page Table

The definition of “performed” given in Books II and III-E applies also to the implicit accesses to the Page Table by the thread in performing address translation. Accesses for performing address translation are considered to be loads in this respect. These implicit accesses are ordered by the sync instruction with L=0 as described below.

The Synchronize instruction is described in Section 4.4.3 of Book II, but only at the level required by an application programmer (sync with L=0 or L=1). This section describes properties of the instruction that are relevant only to operating system and hypervisor software programmers. The sync instruction with L=0 (sync) has the following additional properties.

- The sync instruction provides an ordering function for all stores to the Page Table caused by Store instructions preceding the sync instruction with respect to lookups of the Page Table that are performed, by the thread executing the sync instruction, after the sync instruction completes. Executing a sync instruction ensures that all such stores will be performed, with respect to the thread executing the sync instruction, before any implicit accesses to the affected Page Table Entries, by such Page Table lookups, are performed with respect to that thread.

- In conjunction with the tlbivax and tlbsync instructions, the sync instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the tlbipvax instruction description on page 1141.

Page Table Entry

Each Page Table Entry (PTE) maps a VPN to an RPN. If the corresponding indirect TLB entry has an LPID <E.HV> or PID value of zero, multiple VPNs are mapped by a single PTE in a Page Table pointed to by

Programming Note

For instructions following a sync instruction, the memory barrier need not order implicit storage accesses for purposes of address translation.
such an indirect TLB entry. Figure 24 shows the layout of a PTE.

---

**Programming Note**

Unlike many architectures, the R and C bits in a Page Table entry are not updated by hardware.

---

**Page Table Size and Alignment**

A Page Table's size is $8 \times 2^{(\text{SIZE} - \text{SPSIZE})}$, where SIZE is the page size specified by the SIZE field of the indirect TLB entry used to access the Page Table and SPSIZE is the sub-page size specified by the SPSIZE field of this indirect TLB entry. Page Table sizes smaller than 2 KB are not allowed and SPSIZE must be greater than or equal to 2. This implies that the Page Table size is $2^{k} \leq s \leq 4$ GB. The Page Table is aligned on a boundary that is a multiple of its size.

**TLB Update**

As a result of a Page Table translation, a corresponding direct TLB entry is created if no exception occurs, is optionally created if certain exceptions occur, and is not created if certain other exceptions occur.

If no exception occurs, a direct TLB entry is written to create an entry corresponding to the virtual address and the contents of the PTE that was used to translate the virtual address. In this case, hardware selects the TLB array and TLB entry to be written. Any TLB array
that meets all the following criteria can be selected by the hardware.

- The TLB array supports the page size specified by PTEPS.
- The TLB array can be loaded from the Page Table (TLBnCFGPT = 1).

If no TLB array can be selected based on these criteria, then a TLB Ineligible exception occurs. Hardware also selects the entry within the TLB array based on some implementation-dependent algorithm. However, a valid TLB entry with IPROT = 1 must not be overwritten. If all TLB entries that can be used for a specific virtual page have IPROT = 1, then a TLB Ineligible exception occurs. In the absence of a higher priority exception, an Instruction Storage or Data Storage interrupt occurs, depending on whether the Page Table translation was due to an instruction fetch or data access and ESRTLBI is set to 1.

It is implementation-dependent whether a TLB entry is written as a result of a Page Table translation if a Page Table Fault exception occurs, but, if written, the valid bit of the TLB entry is set to 0. It is implementation-dependent whether a TLB entry is written as a result of a Page Table translation if an Execute, Read, or Write Access Control exception occurs. If the Embedded Hypervisor category is supported, an interrupt caused by a Page Table Translation is directed to the hypervisor or guest as specified by the applicable EPCR bits (DSIGS and ISIGS), except that a DSI or ISI resulting from a TLBI is always directed to the hypervisor.

A TLB entry is not written as a result of a Page Table translation if an LRAT Miss exception occurs or a TLB Ineligible exception occurs.

If a TLB entry is written, the entry is written based on the values shown in Table 7.
If implementations write TLB entries for out-of-order Page Table translations, a mechanism for disabling such TLB updates must be provided by the implementation in order for software to preload a TLB array without the possibility of creating multiple direct entries for the same virtual address.

### Programming Note

As a hardware simplification the architecture allows a TLB entry to be written with the valid bit set to 0 if a Page Table Fault exception occurs. A replacement of a valid TLB entry by an invalid entry is typically not a significant performance impact since software often swaps in the virtual page and creates a valid PTE for the page.

---

### 6.7.5 Page Table Update Synchronization Requirements [Category: Embedded.Page Table]

This section describes rules that software must follow when updating the Page Table. Otherwise, TLB entries for outdated PTEs may remain valid. This section includes suggested sequences of operations for some representative cases.

In the sequences of operations shown in the following subsections, any alteration of a Page Table Entry (PTE) that corresponds to a single line in the sequence is assumed to be done using a Store instruction for which the access is atomic. Appropriate modifications must be made to these sequences if this assumption is not satisfied (e.g., if a store doubleword operation is done using two Store Word instructions).

As described in Section 6.5, stores are not performed out-of-order. Moreover, address translations associated with instructions preceding the corresponding Store instructions are not performed again after the stores have been performed. (These address translations must have been performed before the store was determined to be required by the sequential execution model, because they might have caused an exception.) As a result, an update to a PTE need not be preceded by a context synchronizing operation.

All of the sequences require a context synchronizing operation after the sequence if the new contents of the PTE are to be used for address translations associated with subsequent instructions.

As noted in the description of the Synchronize instruction in Section 4.4.3 of Book II, address translation...
associated with instructions which occur in program order subsequent to the Synchronize may actually be performed prior to the completion of the Synchronize. To ensure that these instructions and data which may have been speculatively fetched are discarded, a context synchronizing operation is required.

**Programming Note**
In many cases this context synchronization will occur naturally; for example, if the sequence is executed within an interrupt handler the rfi instruction that returns from the interrupt handler may provide the required context synchronization.

Page Table Entries must not be changed in a manner that causes an implicit branch.

### 6.7.5.1 Page Table Updates

When Page Tables are in use, TLBs are non-coherent caches of the Page Table. TLB entries must be invalidated explicitly with one of the methods described in Section 6.11.4.3.

Unsynchronized lookups in the Page Table continue even while it is being modified. Any thread, including a thread on which software is modifying the Page Table, may look in the Page Table at any time in an attempt to translate a virtual address. When modifying a PTE, software must ensure that the PTE's Valid bit is 0 if the PTE is inconsistent (e.g., if the BAP field is not correct for the current ARPN field).

The sequences of operations shown in the following subsections assume a multi-threaded processor environment. In a system consisting of only a single-threaded processor the tlbsync must be omitted, and the mbar that separates the tlbivax from the tlb-sync can be omitted. In a multi-threaded processor environment, when tlbilx is used instead of tlbivax in a Page Table update, the synchronization requirements are the same as when tlbivax is used in a system consisting of only a single-threaded processor.

---

**Programming Note**
For all of the sequences shown in the following subsections, if it is necessary to communicate completion of the sequence to software running on another thread, the sync instruction at the end of the sequence should be followed by a Store instruction that stores a chosen value to some chosen storage location X. The memory barrier created by the sync instruction ensures that if a Load instruction executed by another thread returns the chosen value from location X, the sequence's stores to the Page Table have been performed with respect to that other thread. The Load instruction that returns the chosen value should be followed by a context synchronizing instruction in order to ensure that all instructions following the context synchronizing instruction will be fetched and executed using the values stored by the sequence (or values stored subsequently). (These instructions may have been fetched or executed out-of-order using the old contents of the PTE.)

This Note assumes that the Page Table and location X are in storage that is Memory Coherence Required.

### 6.7.5.1.1 Adding a Page Table Entry

This is the simplest Page Table case. The Valid bit of the old entry is assumed to be 0. The following sequence can be used to create a PTE, maintain a consistent state, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

```asm
PTEARPN, WIMGE, R, SN0, C, PS, BAP, SW1, V /* new values
sync /* order updates before next Page Table lookup and before next data access. */
```
On a 32-bit implementation, the following sequence can be used.

```
PTEARPN(0:31) ← new value  
mbar /* order 1st update before 2nd */  
PTEARPN[32:39],MULX,R,SW0,C,PS,BAP,SW1,V ← new values  
sync /* order updates before next  
   Page Table lookup and before  
   next data access. */
```

### 6.7.5.1.2 Deleting a Page Table Entry

The following sequence can be used to ensure that the translation instantiated by an existing entry is no longer available.

```
PTEV ← 0 /* (other fields don’t matter) */  
sync /* order update before tlbivax and  
   before next Page Table lookup */  
tlbivax(old_LPID,old_GS,old_PID,old_AS,old_VA,  
   old_ISIZE, old_IND) /* invalidate old translation*/  
mbar /* order tlbivax before tlbsync */  
tlbsync /* order tlbivax before sync */  
sync /* order tlbivax, tlbsync, and update  
   before next data access */
```

### 6.7.5.1.3 Modifying a Page Table Entry

#### General Case

If a valid entry is to be modified and the translation instantiated by the entry being modified is to be invalidated, the old PTE can be deleted and a new one added using the sequences described in the two preceding sections, in order to ensure that the translation instantiated by the old entry is no longer available, maintain a consistent state, modify the PTE, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

#### Modifying the SW0 and SW1 Fields

If the only change being made to a valid entry is to modify the SW0 or SW1 fields, the following sequence suffices because the SW0 and SW1 fields are not used by the thread.

```
loop:
   ldarx r1 /* load of PTE */  
   r1 ← new SW0,SW1 /* replace SW0,SW1 in r1*/  
   stdcx. PTE ← r1 /* store of PTE  
   if still reserved (new SW0 or SW1  
   values, other fields unchanged) */  
   bne- loop /* loop if lost reservation */
A lwarx/stdcx. pair (specifying the low-order word of the PTE) can be used instead of the ldarx/stdcx. pair shown above.
```

#### Modifying a Reference or Change Bit

If the only change being made to a valid entry is to modify the R bit, the C bit or both, the preceding sequence suffices if the precise instant that hardware Page Table translations use the new value doesn’t matter. Reference, Change, and Valid bits are in different bytes to facilitate the use of a Store instruction of a byte to modify a Reference or Change bit instead of a ldarx and stdcx. However, the correctness of doing so is a software issue beyond the scope of this architecture.

### 6.7.5.2 Invalidating an Indirect TLB Entry

The following sequence can be used to ensure that translations by a Page Table that is mapped via an indirect entry will no longer occur and that the storage used for the Page Table can then be re-used for other purposes.

```
for all valid PTEs mapped by the indirect TLB entry
   PTEV ← 0 /* (other fields don’t matter) */  
   sync /* order stores to PTEs */  
for all valid PTEs mapped by the indirect TLB entry
   tlbivax(old_LPID,old_GS,old_PID,old_AS,old_VA,  
   old_ISIZE, MAS6SIND = 0) /* invalidate old PTE translations*/  
   mbar /* order tlbivax before tlbsync */  
   tlbsync /* order tlbivax before sync */  
   sync /* order tlbivax, tlbsync, and update  
   before next data access to the storage  
   locations occupied by the Page Table  
   pointed to by the old indirect TLB */
```

### 6.7.6 Storage Access Control

After a matching TLB entry has been identified, the access control mechanism selectively grants execute access, read access, and write access separately for user mode versus supervisor mode. If the Embedded.Hypervisor category is supported, the access control mechanism selectively controls an access so that the access can be virtualized by the hypervisor if appropriate. Figure 25 illustrates the access control process and is described in detail in Sections 6.7.6.1 through 6.7.6.6.

An Execute, Read, or Write Access Control exception or Virtualization Fault exception occurs if the appropriate TLB entry is found but the access is not allowed by the access control mechanism (Instruction or Data Storage interrupt). See Section 7.6 for additional information about these and other interrupt types. In certain cases, Execute, Read, and Write Access Control exceptions and Virtualization Fault exceptions may result in the restart of (re-execution of at least part of) a Load or Store instruction.

Implementations may provide additional access control capabilities beyond those described here.
6.7.6.1 Execute Access

The UX and SX bits of the TLB entry control execute access to the page (see Table 8).

Instructions may be fetched and executed from a page in storage while in user state (MSR PR=1) if the UX access control bit for that page is equal to 1. If the UX access control bit is equal to 0, then instructions from that page will not be fetched, and will not be placed into any cache as the result of a fetch request to that page while in user state.

Instructions may be fetched and executed from a page in storage while in supervisor state (MSR PR=0) if the SX access control bit for that page is equal to 1. If the SX access control bit is equal to 0, then instructions from that page will not be fetched, and will not be placed into any cache as the result of a fetch request to that page while in supervisor state.

Instructions from no-execute storage may be in the instruction cache if they were fetched into that cache when their effective addresses were mapped to execute permitted storage. Software need not flush a page from the instruction cache before marking it no-execute.

Furthermore, if the sequential execution model calls for the execution of an instruction from a page that is not enabled for execution (i.e. UX=0 when MSR PR=1 or SX=0 when MSR PR=0), an Execute Access Control exception type Instruction Storage interrupt is taken.

6.7.6.2 Write Access

The UW and SW bits of the TLB entry control write access to the page (see Table 8).

Store operations (including Store-class Cache Management instructions) are permitted to a page in storage while in user state (MSR PR=1) if the UW access control bit for that page is equal to 1. If the UW access control bit is equal to 0, then execution of the Store instruction is suppressed and a Write Access Control exception type Data Storage interrupt is taken.

Store operations (including Store-class Cache Management instructions) are permitted to a page in storage while in supervisor state (MSR PR=0) if the SW access control bit for that page is equal to 1. If the SW access control bit is equal to 0, then execution of the Store instruction is suppressed and a Write Access Control exception type Data Storage interrupt is taken.

6.7.6.3 Read Access

The UR and SR bits of the TLB entry control read access to the page (see Table 8).

Load operations (including Load-class Cache Management instructions) are permitted from a page in storage while in user state (MSR PR=1) if the UR access control bit for that page is equal to 1. If the UR access control bit is equal to 0, then execution of the Load instruction is suppressed and a Read Access Control exception type Data Storage interrupt is taken.

Load operations (including Load-class Cache Management instructions) are permitted from a page in storage while in supervisor state (MSR PR=0) if the SR access control bit for that page is equal to 1. If the SR access...
control bit is equal to 0, then execution of the Load instruction is suppressed and a Read Access Control exception type Data Storage interrupt is taken.

6.7.6.4 Virtualized Access <E.HV>

The VF bit of the TLB entry prevents a Load or Store access to the page (see Table 8).

The translation of a Load or Store (including Cache Management instructions) operand address that uses a TLB entry with the Translation Virtualization Fault field equal to 1 causes a Virtualization Fault exception type Data Storage interrupt regardless of the settings of the permission bits and regardless of whether the TLB entry is a direct or indirect entry. The resulting Data Storage interrupt is directed to the hypervisor state.

6.7.6.5 Storage Access Control Applied to Cache Management Instructions

dcbi, dci, dcbz, and dcbzep instructions are treated as Stores since they can change data (or cause loss of data by invalidating dirty lines). As such, they can cause Write Access Control exception type Data Storage interrupts and Virtualization Fault exception type Data Storage interrupts. If an implementation first flushes a line before invalidating it during a dcbi, the dcbi is treated as a Load since the data is not modified.

dcba instructions are treated as Stores since they can change data. However, they do not cause Write Access Control exceptions. A dcba instruction will not cause a virtualization fault (TLBVF = 1).

dcbt, dcbtep, and icbt instructions are treated as Loads with respect to protection. However, they do not cause Read Access Control exceptions. A virtualization fault on these instructions will not result in a Data Storage interrupt.

dcbst and dcbstep instructions are treated as Stores with respect to protection. However, they do not cause Write Access Control exceptions. A virtualization fault on these instructions will not result in a Data Storage interrupt.

It is implementation-dependent whether dcbtstls instructions are treated as Loads or Stores with respect to protection. As such, they can cause either Load Access Control exception type Data Storage interrupts or Write Access Control exception type Data Storage interrupts and can also cause Virtualization Fault exception type Data Storage interrupts.

dcbf, dcbfep, dcbst, and dcbstep instructions are treated as Loads with respect to protection. Flushing or storing a line from the cache is not considered a Store since the store has already been done to update the cache and the dcbf, dcbfep, dcbst, or dcbstep instruction is only updating the copy in main storage. As a Load, they can cause Read Access Control exception type Data Storage interrupts and Virtualization Fault exception type Data Storage interrupts.

</table>

1. Category: Embedded.Hypervisor
2. icbtl and icbic require execute or read access.
3. dcbi may cause a Read or Write Access Control Exception based on whether the data is flushed prior to invalidation.
4. It is implementation-dependent whether dcbtstls is treated as a Load or a Store.
5. If an exception is detected, the instruction is treated as a no-op and no interrupt is taken.

6.7.6.6 Storage Access Control Applied to String Instructions

When the string length is zero, neither lswx nor stswx can cause Data Storage interrupts.
6.8 Storage Control Attributes

This section describes aspects of the storage control attributes that are relevant only to privileged software programmers. The rest of the description of storage control attributes may be found in Section 1.6 of Book II and subsections.

6.8.1 Guarded Storage

Storage is said to be “well-behaved” if the corresponding real storage exists and is not defective, and if the effects of a single access to it are indistinguishable from the effects of multiple identical accesses to it. Data and instructions can be fetched out-of-order from well-behaved storage without causing undesired side effects.

Storage is said to be Guarded if the G bit is 1 in the TLB entry that translates the effective address.

In general, storage that is not well-behaved should be Guarded. Because such storage may represent a control register on an I/O device or may include locations that do not exist, an out-of-order access to such storage may cause an I/O device to perform unintended operations or may result in a Machine Check.

Instruction fetching is not affected by the G bit.

The following rules apply to in-order execution of Load and Store Instructions for which the first byte of the storage operand is in storage that is both Caching Inhibited and Guarded.

- Load or Store instruction that causes an atomic access

  If any portion of the storage operand has been accessed and an asynchronous or imprecise interrupt is pending, the instruction completes before the interrupt occurs.

- Load or Store instruction that causes an Alignment exception, a Data TLB Error exception, or that causes a Data Storage exception.

  The portion of the storage operand that is in Caching Inhibited and Guarded storage is not accessed.

6.8.1.1 Out-of-Order Accesses to Guarded Storage

In general, Guarded storage is not accessed out-of-order. The only exception to this rule is the following.

Load Instruction

If a copy of any byte of the storage operand is in a cache then that byte may be accessed in the cache or in main storage.

6.8.2 User-Definable

User-definable storage control attributes control user-definable and implementation-dependent behavior of the storage system. The existence of these bits is implementation-dependent. These bits are both implementation-dependent and system-dependent in their effect. These bits may be used in any combination and also in combination with the other storage control attribute bits.

6.8.3 Storage Control Bits

Storage control attributes are specified on a per-page basis. These attributes are specified in storage control bits in the TLB entries. The interpretation of their values is given in Figure 26.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Storage Control Attribute</th>
</tr>
</thead>
<tbody>
<tr>
<td>W₁,₆</td>
<td>0 - not Write Through Required</td>
</tr>
<tr>
<td>I₆</td>
<td>0 - not Caching Inhibited</td>
</tr>
<tr>
<td>M₂</td>
<td>0 - not Memory Coherence Required</td>
</tr>
</tbody>
</table>

Programming Note

Instruction fetching from Guarded storage is permitted. If instruction fetches from Guarded storage must be prevented, software must set access control bits for such pages to no-execute (i.e. UX=0 and SX=0).
In Section 6.8.3.1 and 6.8.3.2, "access" includes accesses that are performed out-of-order.

### 6.8.3.1 Storage Control Bit Restrictions

All combinations of W, I, M, G, and E values are permitted except those for which both W and I are 1 and M || G ≠ \[0b10\].

The combination WIMG = \[0b1110\] is used to identify the Strong Access Ordering (SAO) storage attribute (see Section 1.7.1, “Storage Access Ordering”, in Book II). Setting WIMG=\[0b1110\] in a TLB entry causes accesses to the page to behave as if WIMG=\[0b0010\] with additional strong access ordering behavior. Only one SAO setting is provided because this attribute is not intended for general purpose programming, so a single combination of WIMG bits is supported.

If a given real page is accessed concurrently as SAO storage and as non-SAO storage, the result may be characteristic of the weakly consistent model.

**Programming Note**

If an application program requests both the Write Through Required and the Caching Inhibited attributes for a given storage location, the operating system should set the I bit to 1 and the W bit to 0. For implementations that support the SAO category, the operating system should provide a means by which application programs can request SAO storage, in order to avoid confusion with the preceding guideline (since SAO is encoded using \(W=0b11\)).

Accesses to the same storage location using two effective addresses for which the W bit differs meet the memory coherence requirements described in Section 1.6.3 of Book II if the accesses are performed by a single thread. If the accesses are performed by two or more threads, coherence is enforced by the hardware only if the W bit is the same for all the accesses.

At any given time, the value of the I bit must be the same for all accesses to a given real page.

At any given time, data accesses to a given real page may use both Endian modes. When changing the Endian mode of a given real page for instruction fetching, care must be taken to prevent accesses while the change is made and to flush the instruction cache(s) after the change has been completed.

Setting the VLE attribute to 1 and setting the E attribute to 1 is considered a programming error and an attempt to fetch instructions from a page so marked produces an Instruction Storage Interrupt Byte Ordering Exception and sets ESRBO or GESRBO to 1 (GESRBO if the Embedded.Hypervisor category is supported and the interrupt is directed to the guest. Otherwise, ESRBO).

At any given time, the value of the VLE bit must be the same for all accesses to a given real page.

### References to Caching Inhibited storage

References to Caching Inhibited storage (or storage with \(I=1\)) elsewhere in the Power ISA have no application to SAO storage or its WIMG encoding, despite the fact that the encoding uses \(I=1\). Conversely, references to storage that is not Caching Inhibited (or storage with \(I=0\)) apply to SAO storage or its WIMG encoding. References to Write Through Required storage (or storage with \(W=1\)) elsewhere in the Power ISA have no application to SAO storage or its WIMG encoding, despite the encoding using \(W=1\). Conversely, references to storage that is not Write Through Required (or storage with \(W=0\)) apply to SAO storage or its WIMG encoding.

**Figure 26. Storage control bits**

In Section 6.8.3.1 and 6.8.3.2, “access” includes accesses that are performed out-of-order.

<table>
<thead>
<tr>
<th>Bit</th>

</tbody>
</table>

1. Support for the 1 value of the W bit is optional. Implementations that do not support the 1 value treat the bit as reserved and assume its value to be 0.
2. Support of the 1 value is optional for implementations that do not support multiprocessing, implementations that do not support this storage control attribute assume the value of the bit to be 0, and setting M=1 in a TLB entry will have no effect.
3. [Category: Embedded.Little-Endian]
4. Support for these attributes is optional.
5. [Category: VLE]
6. [Category: SAO] The combination WIMG = \[0b1110\] has behavior unrelated to the meanings of the individual bits. See Section 6.8.3.1, “Storage Control Bit Restrictions” for additional information.
7. The coherency method used in Alternate Coherency Mode is implementation-dependent.

### Programming Note

In a system consisting of only a single-threaded processor that has caches, correct coherent execution does not require storage to be accessed as Memory Coherence Required, and accessing storage as not Memory Coherence Required may give better performance.
6.8.3.2 Altering the Storage Control Bits

When changing the value of the W bit for a given real page from 0 to 1, software must ensure that no thread modifies any location in the page until after all copies of locations in the page that are considered to be modified in the data caches have been copied to main storage using `dcbst`, `dcbstep`, `dcbf`, `dcbfep`, or `dcbi`.

When changing the value of the I bit for a given real page from 0 to 1, software must set the I bit to 1 and then flush all copies of locations in the page from the caches using `dcbf`, `dcbfep`, or `dcbi`, and `icbi` or `icbiep` before permitting any other accesses to the page.

When changing the value of the M bit for a given real page, software must ensure that all data caches are consistent with main storage. The actions required to do this to are system-dependent.

When changing the value of the ACM bit for a given real page are system-dependent.

When changing the value of the VLE bit for a given real page, software must set the VLE bit to the new value, then, if the page was not Caching Inhibited, invalidate copies of all locations in the page from instruction cache using `icbi` or `icbiep`, and then execute an `isync` instruction before permitting any other accesses to the page.
Programming Note

This Note suggests one example for managing reference and change recording.

When performing physical page management, it is useful to know whether a given physical page has been referenced or altered. Note that this may be more involved than knowing whether a given TLB entry has been used to reference or alter memory, since multiple TLB entries may translate to the same physical page. If it is necessary to replace the contents of some physical page with other contents, a page which has been referenced (accessed for any purpose) is more likely to be retained than a page which has never been referenced. If the contents of a given physical page are to be replaced, then the contents of that page must be written to the backing store before replacement, if anything in that page has been changed. Software must maintain records to control this process.

Similarly, when performing TLB management, it is useful to know whether a given TLB entry has been referenced. When making a decision about which entry to cast-out of the TLB, an entry which has been referenced is more likely to be retained in the TLB than an entry which has never been referenced.

Execute, Read and Write Access Control exceptions may be used to allow software to maintain reference information for a TLB entry and for its associated physical page. The entry is built, with its UX, SX, UR, SR, UW, and SW bits off, and the index and effective page number of the entry retained by software. The first attempt of application code to use the page will cause an Access Control exception (because the entry is marked “No Execute”, “No Read”, and “No Write”). The Instruction or Data Storage interrupt handler records the reference to the TLB entry and to the associated physical page in a software table, and then turns on the appropriate access control bit. An initial read from the page could be handled by only turning on the appropriate UR or SR access control bits, leaving the page “read-only”.

In a demand-paged environment, when the contents of a physical page are to be replaced, if any storage in that physical page has been altered, then the backing storage must be updated. The information that a physical page is dirty is typically recorded in a “Change” bit for that page.

Write Access Control exceptions may be used to allow software to maintain change information for a physical page. For the example just given for reference recording, the first write access to the page via the TLB entry will create a Write Access Control exception type Data Storage interrupt. The Data Storage interrupt handler records the change status to the physical page in a software table, and then turns on the appropriate UW and SW bits.
6.9 Logical to Real Address Translation [Category: Embedded.Hypervisor.LRAT]

In a partitioned environment, a guest operating system is not allowed to manipulate real page numbers. Instead the hypervisor virtualizes the real memory and the guest operating system manages the virtualized memory using logical page numbers (LPNs). In MMU Architecture Version 2.0, a Logical to Real Address Translation (LRAT) array facilitates this virtualization by providing a hardware translation from an LPN to an RPN without trapping to the hypervisor for every TLB update.

LRAT Entry

Below are shown the field definitions for an LRAT entry.

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>V</td>
<td>Valid This bit indicates that this LRAT entry is valid and may be used for translation of an LPN to an RPN. The Valid bit for a given entry can be set or cleared with a <code>tlbwe</code> instruction.</td>
</tr>
<tr>
<td>LPID</td>
<td>Logical Partition ID This optional field identifies a partition. The Logical Partition ID is compared with LPIDR contents during an LRAT translation. This field is required if category E.PT is supported or if threads that share an LRAT can be in different partitions. Whether the LPID field is supported is indicated by LRATCFGLPID. Note: The number of bits implemented for this field is required to be the same as the TLPID field in a TLB.</td>
</tr>
<tr>
<td>LPN</td>
<td>Logical Page Number (up to 54 bits) Bits 64-qn-1 of the LPN field are compared to bits 64-qn-1 of the Logical Page Number (LPN) for the <code>tlbwe</code> instruction or Page Table translation (where q = LRATCFG_LASIZE and n = 64 - log2(smallest logical page size in bytes) and logical page size is specified by the LSIZE field of the LRAT entry). See Section 6.7.2. Software must set unused low-order LPN bits to 0. Note: Bits X:Y of the LPN field are implemented, where X ≥ 0 and Y ≤ 53. The bits implemented for LPN are required to be the same as those implemented for TLBRPN. Unimplemented LPN bits are treated as if they contain 0s.</td>
</tr>
<tr>
<td>LSIZE</td>
<td>Logical Page Size The LSIZE field specifies the size of the logical page associated with the LRAT entry as 2^{LSIZE}, where 0 ≤ LSIZE ≤ 31. Implementations may support any one or more of these logical page sizes (see Section 6.10.3.6), and these logical page sizes need not be the same as the real page sizes that are implemented. However, the smallest logical page is no smaller than the smallest real page. The encodes for LSIZE are the same as the encodes for the TLB SIZE. See Section 6.7.2. This field must be one of the logical page sizes specified by the LRATPS register.</td>
</tr>
<tr>
<td>LRPN</td>
<td>LRAT Real Page Number (up to 54 bits) Bits 0:n-1 of the LRPN field are used to replace bits 0:n-1 of the LPN to produce the RPN that is written to TLBRPN by a <code>tlbwe</code> instruction or a Page Table translation (where n = 64 - log2(smallest logical page size in bytes) and logical page size is specified by the LSIZE field of the LRAT entry). Software must set unused low-order LRPN bits to 0. Note: Bits X:Y of the LRPN field are implemented, where X ≥ 0 and Y ≤ 53. X = 64 - MMUCFG_RASIZE, Y = p - 1 where p = 64 - log2(smallest logical page size in bytes) and smallest logical page size is the smallest page size supported by the implementation as specified by the LRATPS register. Unimplemented LRPN bits are treated as if they contain 0s.</td>
</tr>
</tbody>
</table>

An LRAT entry can be written by the hypervisor using the `tlbwe` instruction with MAS0_ATSEL equal to 1. The contents of the LRAT entry specified by MASDESEL and MAS2EPN are written from MAS registers. See the `tlbwe` instruction description in Section 6.11.4.9.

An LRAT entry can be read by the hypervisor using the `tlbre` instruction with MAS0_ATSEL equal to 1. The contents of the LRAT entry specified by MASDESEL and MAS2EPN are read and placed into the MAS registers. See the `tlbre` instruction description in Section 6.11.4.9.

Maintenance of LRAT entries is under hypervisor software control. Hypervisor software determines LRAT entry replacement strategy. There is no Next Victim support for the LRAT array.

The LRAT array is a hypervisor resource.

There is at most one LRAT array per thread.
Programming Note

Hypervisor software should not create an LRAT entry that maps any real memory regions for which a TLB entry should have VF equal to 1. Otherwise, a guest operating system could incorrectly create TLB entries, for this memory, with VF=0, assuming hypervisor software normally sets MAS8VF=0 before giving control to a guest operating system.

TLB Write

When the guest operating system manipulates the values of RPN fields of MAS registers, the values are treated as forming an LPN. When guest supervisor software attempts to execute `tlbwe` on an implementation that supports MMU Architecture Version 1, `tlbre`, and `tlbsx`, which operate on a TLB entry’s real page number (RPN) or when guest supervisor software attempts to execute a TLB Management instruction with guest execution of TLB Management instructions disabled (EPCR DGTMI=1), an Embedded Hypervisor Privilege exception occurs. Also, if TLBnCFG GTWE = 0 for a TLB array and the guest supervisor executes a `tlbwe` to the TLB array, an Embedded Hypervisor Privilege exception occurs. If a `tlbwe` caused the exception, the hypervisor can replace the LPN value in the MAS registers with the corresponding RPN, execute a `tlbwe`, and restore the LPN in the MAS registers before returning to the guest operating system. If a `tlbre` or `tlbsx` caused the exception, the hypervisor can execute the exception-causing instruction and replace the RPN value in the MAS registers with the corresponding LPN before returning to the guest operating system.

A Logical to Real Address Translation (LRAT) array provides a mechanism that allows a guest operating system to write the TLB without trapping to the hypervisor. When guest supervisor software executes `tlbwe` on an implementation that supports MMU Architecture Version 2, guest execution of TLB Management instructions is enabled (EPCR DGTMI=0), and TLBnCFG GTWE = 1 for the TLB array to be written, an LPN is formed. If MAS7 is implemented, LPN = MAS7RNNU || MAS3RPNL. Otherwise, LPN = 350 || MAS3RPNL. The LPN is translated into an RPN by the LRAT if a matching LRAT entry is found. A matching LRAT entry exists if the following conditions are all true for some LRAT entry:

The Valid bit of the LRAT entry is one.

Either the LPID field is not supported in the LRAT (LRATCFGLPID=0) or the value of LPIDR LPID is equal to the value of the LPID field of the LRAT entry.

Bits 64-q:n-1 of the LPN match the corresponding bits of the LPN field of the LRAT entry where n = 64 – \( \log_2(\text{logical page size in bytes}) \), \( \text{logical page size} \) is specified by the LSIZE field of the LRAT entry, and q is specified by LRATCFGLASIZE.

Either of the following is true:

- \( \text{MAS1}_{\text{IND}} = 0 \) and the value of \( \text{MAS1}_{\text{TSIZE}} \) is less than or equal to the value of the LSIZE field of the LRAT entry.
- \( \text{MAS1}_{\text{IND}} = 1 \) and the value of \( (3 + (\text{MAS1}_{\text{TSIZE}} - \text{MAS3SPSIZE})) \) is less than or equal to the value of the \( (10 + \text{LRAT entry}_{\text{LSIZE}}) \).

If a matching LRAT entry is found, the LRPN from that LRAT entry provides the upper bits of the RPN that is written to the TLB, and the LPN provides the low order RPN bits written to the TLB. Let \( n=64-\log_2(\text{logical page size in bytes}) \) where \( \text{logical page size} \) is specified by the LSIZE field of the LRAT entry. Bits \( n:53 \) of the LPN are appended to bits 0:n–1 of the LRPN field of the selected LRAT entry to produce the RPN (i.e., \( \text{RPN} = \text{LRPN}_{0:n-1} || \text{LPN}_{n:53} \)). The page size specified by the LSIZE of the LRAT entry used to translate the LPN must be one of the values supported by the implementation’s LRAT array. If the LRAT does not contain a matching entry for the LPN, an LRAT Miss exception occurs.

When the hypervisor executes a `tlbwe` instruction, no LRAT translation is performed and the RPN formed from MAS7RNNU and MAS3RPNL is written to the TLB.

Page Table

A Logical to Real Address Translation (LRAT) array provides a mechanism that allows guest Page Table management and translation without direct hypervisor involvement. When an instruction fetch address or a Load, Store, or Cache Management instruction operand address is translated by the Page Table, the Embedded.Hypervisor category is supported, and the TGS bit of the associated indirect TLB entry is 1, the RPN result of the Page Table translation is treated as an LPN that is translated into an RPN by the LRAT if a matching LRAT entry is found. A matching LRAT entry exists if the following conditions are all true for some LRAT entry:

The Valid bit of the LRAT entry is one.

Either the LPID field is not supported in the LRAT (LRATCFGLPID=0) or the value of LPIDR LPID is equal to the value of the LPID field of the LRAT entry.

Bits 64-q:n-1 of the LPN match the corresponding bits of the LPN field of the LRAT entry where \( n = 64 – \log_2(\text{logical page size in bytes}) \), \( \text{logical page size} \) is specified by the LSIZE field of the LRAT entry, and q is specified by LRATCFGLASIZE.

The value of PTEPS is less than or equal to the value of the LSIZE field of the LRAT entry.

If a matching LRAT entry is found, the LRPN from that LRAT entry provides the upper bits of the RPN of the translation result and the LPN provides the low order RPN bits of the translation result. Let \( n=64-\log_2(\text{logical page size in bytes}) \) where \( \text{logical page size} \) is specified by the LSIZE field of the LRAT entry. Bits
Chapter 6. Storage Control

6.10 Storage Control Registers

In addition to the registers described below, the Machine State Register provides the IS and DS bits, that specify which of the two address spaces the respective instruction or data storage accesses are directed towards. MSRPR bit is also used by the storage access control mechanism. If the Embedded.Hypervisor category is supported, the MSRGS bit is used to identify guest state. The guest supervisor state exists when MSRPR = 0 and MSRGS = 1. MSRGS is used to form the virtual address. Also, see Section 5.3.7 for the registers in the Embedded.External PID category.

6.10.1 Process ID Register

The Process ID Registers are 32-bit registers as shown in Figure 27. Process ID Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The number of bits implemented in a PID register is indicated by the value of the MMUCFG_PIDSIZE. The Process ID Register provides a value that is used to construct a virtual address for accessing storage.

The Process ID Register is a privileged register. This register can be read using mfspr and can be written using mtspr. An implementation may opt to implement only the least-significant \( n \) bits of the Process ID Register, where \( 1 \leq n \leq 14 \), and \( n \) must be the same as the number of implemented bits in the TID field of the TLB entry. The most-significant \( 32-n \) bits of the Process ID Register are treated as reserved.

Figure 27. Processor ID Register (PID)

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>50:63</td>
<td>Processor ID (PID)</td>
</tr>
</tbody>
</table>

Identifies a unique process (except for the value of 0) and is used to construct a virtual address for storage accesses.

All other fields are reserved.

6.10.2 MMU Assist Registers

The MMU Assist Registers (MAS) are used to transfer data to and from the TLB arrays. If the Embedded.Hypervisor.LRAT category is supported, MAS registers are also used to transfer data to and from the LRAT array. MAS registers can be read and written by software using mfspr and mtspr instructions. Execution of a tlbre instruction with MAS0_ATSEL=0 causes the TLB entry specified by MAS0_TLBSEL, MAS0_ESEL, and MAS2_EPN to be copied to the MAS registers if TLBnCFGHES = 0 for the TLB array specified by MAS0_TLBSEL whereas the TLB entry is specified by MAS0_ESEL, MAS0_TLBSEL, and a hardware generated hash based on MAS2_EPN, MAS1_TID, and MAS1_TSIZE if TLBnCFGHES=1. Execution of a tlbwe instruction with MAS0_ATSEL=0 (or in guest supervisor state) causes the TLB entry specified by MAS0_TLBSEL, MAS0_ESEL, and MAS2_EPN to be written with contents of the MAS registers if TLBnCFGHES = 0 for the TLB array specified by MAS0_TLBSEL. If TLBnCFGHES = 1 for a tlbwe, the TLB entry is selected by MAS0_TLBSEL, a hardware generated hash based on MAS2_EPN, MAS1_TID, and MAS1_TSIZE, and either a hardware replacement algorithm if MAS0_HES=1 or MAS0_ESEL if MAS0_HES=0.

MAS registers may also be updated by hardware as the result of any of the following.

- A tlbx instruction
- The occurrence of an Instruction or Data TLB Error interrupt if any of the following is true.
  - The Embedded.Hypervisor category is not supported.
  - MAS Register updates are enabled for interrupts directed to the hypervisor (EPCR_MUH = 0).
  - The interrupt is directed to the guest state (EPCR_TLBGS = 1 for Instruction TLB Error interrupt and EPCR_DTLBGS = 1 for Data TLB Error interrupt).

All MAS registers are privileged, except MAS5 and MAS8, which are hypervisor privileged and are only provided if Category: Embedded.Hypervisor is supported. All MAS registers with the exception of MAS7 and, if Embedded.Hypervisor category is not supported, MAS5 and MAS8, must be implemented. MAS7 is not required to be implemented if the hardware supports 32 bits or less of real address.

The necessary bits of any multi-bit field in a MAS register must be implemented such that only the resources supported are represented. Any non-implemented bits in a field should have no effect when writing and should always read as zero. For example, if only 2 TLB arrays...
are implemented, then only the lower-order bit of the MAS0TLBSEL field is implemented.

**Programming Note**

Operating system developers should be wary of new implementations silently ignoring unimplemented MAS bits on MAS register writes. This is a common error during initial bring-up of a new processor.

### 6.10.3 MMU Configuration and Control Registers

#### 6.10.3.1 MMU Configuration Register (MMUCFG)

The read-only MMUCFG register provides information about the MMU and its arrays. MMUCFG is a privileged register except that if the Embedded.Hypervisor category is supported, MMUCFG is a hypervisor resource. The layout of the MMUCFG register is shown in Figure 28 for MAV=1.0 and in Figure 29 for MAV=2.0.

**Figure 28. MMU Configuration Register [MAV=1.0]**

```
+----------+----------+----------+----------+----------+----------+
| 32 36 40 47 53 58 60 62 63 |
| LPIDSIZE | RASIZE   | PIDSIZE  | NTLBS    | MAVN     |
+----------+----------+----------+----------+----------+
```

**Figure 29. MMU Configuration Register [MAV=2.0]**

```

| 32 36 40 47 48 49 53 58 60 62 63 |
| LPIDSIZE | RASIZE   | LRAT     | TWC      | PIDSIZE  | NTLBS    | MAVN     |
+----------+----------+----------+----------+----------+----------+----------+
```

The MMUCFG fields are described below.

**Bit Description**

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>36:39</td>
<td><strong>LPID Register Size</strong> (LPIDSIZE) The value of LPIDSIZE is the number of bits in LPIDR that are implemented. Only the least significant LPIDSIZE bits in LPIDR are implemented. The Embedded.Hypervisor category is supported if and only if LPIDSIZE &gt; 0.</td>
</tr>
<tr>
<td>40:46</td>
<td><strong>Real Address Size</strong> (RASIZE) Number of bits in a real address supported by the implementation.</td>
</tr>
<tr>
<td>47</td>
<td><strong>LRAT Translation Supported</strong> (LRAT) [Category: Embedded.Hypervisor.LRAT] Indicates LRAT translation is supported. 0 LRAT translation is not supported. A tlbw executed in guest supervisor state results in an Embedded Hypervisor Privilege exception.</td>
</tr>
<tr>
<td>53</td>
<td><strong>PID Register Size</strong> (PIDSIZE) The value of PIDSIZE is one less than the number of bits implemented for each of the PID registers implemented. Only the least significant PIDSIZE+1 bits in the PID registers are implemented. The maximum number of PID register bits that may be implemented is 14.</td>
</tr>
<tr>
<td>60:61</td>
<td><strong>Number of TLBs</strong> (NTLBS) The value of NTLBS is one less than the number of software-accessible TLB structures that are implemented. NTLBS is set to one less than the number of TLB structures so that its value matches the maximum value of MAS0TLBSEL.</td>
</tr>
<tr>
<td>62:63</td>
<td><strong>MMU Architecture Version Number</strong> (MAVN) Indicates the version number of the architecture of the MMU implemented.</td>
</tr>
</tbody>
</table>

All other fields are reserved.

#### 6.10.3.2 TLB Configuration Registers (TLBnCFG)

Each TLBnCFG read-only register provides configuration information about each corresponding TLB array that is implemented. There is one TLBnCFG register implemented for each TLB array that is implemented. TLBnCFG corresponds to TLBn for 0 ≤ n ≤ MMUCFGNTLBS. TLBnCFG registers are privileged registers except that if the Embedded.Hypervisor category is supported, TLBnCFG registers are hypervisor resources. The layout of the TLBnCFG registers is...
shown in Figure 30 for MAV=1.0 and in Figure 31 for MAV=2.0.

Figure 30. TLB Configuration Register [MAV=1.0]

Figure 31. TLB Configuration Register [MAV=2.0]

The TLBnCFG fields are described below.

Bit   Description
-------------------------------------------------------------------------
32:39 Associativity (ASSOC)
       Total number of entries in a TLB array which can be used for       |
       translating addresses with a given EPN. This number is referred   |
       to as the associativity level of the TLB array. Some values of    |
       assoc have special meanings when used in combination with specific |
       values of NENTRY, as follows. However, if TLBnCFG-GHES=1, the    |
       associativity level of the TLB array is implementation dependent. |
40:43 Minimum Page Size (MINSIZE) [MAV=1.0]
       This field defines the minimum page size of the TLB array. Page   |
       size encoding is defined in Section 6.7.2.                         |
44:47 Maximum Page Size (MAXSIZE) [MAV=1.0]
       This field defines the maximum page size of the TLB array. Page    |
       size encoding is defined in Section 6.7.2.                         |
45    Page Table (PT) [MAV=2.0 and Category: E.PT]                     |
       Indicates that the TLB array can be loaded from the hardware Page   |
       Table.
0    TLB array cannot be loaded from the Page Table.
1    TLB array can be loaded from the Page Table.

Indirect (IND) [MAV=2.0 and Category: E.PT] indicates that an indirect TLB entry can be created in the TLB array and that there is a corresponding EPTCFG register that defines the SIZE and Sub-Page Size values that are supported.
0 The TLB array treats the IND bit as reserved.
1 The TLB array supports indirect entries.

Guest TLB Write Enabled (GTWE) [MAV=2.0 and Category: Embedded.Hypervisor.LRAT] indicates that a guest supervisor can write the TLB array because LRAT translation is supported for the TLB array.
0 A guest supervisor cannot write the TLB array. A tlbwe executed in guest supervisor state results in an Embedded Hypervisor Privilege exception.
1 A guest supervisor can write the TLB array if guest execution of TLB Management instructions is enabled (EPCRDGTMI=0).

Invalidate Protection (IPROT) Invalidate protect capability of the TLB array.
0 Indicates invalidate protection capability not supported.
1 Indicates invalidate protection capability supported.

Page Size Availability (AVAIL) [MAV=1.0]
This defines the page size availability of the TLB array. If the Embedded.Page Table category is supported, this also defines the virtual address space size availability of TLB array. Otherwise, this field is reserved.
0 Fixed selectable page size from MINSIZE to MAXSIZE (all TLB entries are the same size).
1 Variable page size from MINSIZE to MAXSIZE (each TLB entry can be sized separately).

Hardware Entry Select (HES) [MAV=2.0]
Indicates whether the TLB array supports MAS0HES and the associated method for hardware selecting a TLB entry based on MAS1TID TSIZE and MAS2EPN for a tlbwe instruction.
0  MAS0HES is not supported.
1  MAS0HES is supported for tlbwe. See Section 6.10.3.8. For tlbre, MAS0ESSEL selects among the TLB entries that can be used for translating addresses with a given MAS1TID TSIZE and MAS2EPN. The set of TLB entries is determined by a hardware generated hash based on MAS1TID TSIZE and MAS2EPN. The hash is the same for tlbwe and tlbre for a given TLB array but could be different for each TLB array.

52:63  **Number of Entries (NENTRY)**

Number of entries in the TLB array.

All other fields are reserved.

### 6.10.3.3 TLB Page Size Registers (TLBnPS) [MAV=2.0]

Each TLBnPS read-only register provides page size information about each corresponding TLB array that is implemented in MMU Architecture Version 2.0. Each Page Size bit (PS0-PS31) that is a one indicates that a specific page size is supported by the array. Multiple 1 bits indicate that multiple page sizes are supported concurrently. TLBnPS registers are privileged registers except that if the Embedded.Hypervisor category is supported, TLBnPS registers are hypervisor resources. The layout of the TLBnPS registers is shown in Figure 32.

**Figure 32. TLB n Page Size Register**
The TLBnPS fields are described below.

#### Bit Description

32:63  **Page Size 31 - Page Size 0 (PS31-PS0)**

PSm indicates whether a direct TLB entry page size of 2^m KB is supported by the TLB array. PSm corresponds to bit TLBnPS_{63-m} for m = 0 to 31.

0  Direct TLB entry page size of 2^m KB is not supported.
1  Direct TLB entry page size of 2^m KB is supported.

Table 9 shows the relationship between the Page Size (PSm) bits in TLBnPS and page size. The existence and type of mechanism for configuring the use of a subset of supported page sizes is implementation-dependent.

### 6.10.3.4 Embedded Page Table Configuration Register (EPTCFG)

This read-only register consists of 3 pairs of page size (PSi) and sub-page size (SPSi) values, where i = 0 to 2. These combinations are supported for Page Table translations. The page size and sub-page size encodings for PSi and SPSi are the same the MAS1FSIZE encodings, except that an SPSi value of 0b00001 is reserved and a value of zero for the SPSi field means there is no page size and sub-page size combination information supplied by that field. If SPSi is zero, PSi is zero. Zero values of PSi and SPSi pairs are the leftmost fields. See Table 3. For nonzero values of SPSi, PSi minus SPSi is greater than 7.

The EPTCFG register is a privileged register except that if the Embedded.Hypervisor category is supported,
EPTCFG register is a hypervisor resource. The layout of the EPTCFG register is shown in Figure 33.

```
   //    PS2   SPS2   PS1   SPS1   PS0   SPS0
32  34  39  44  49  54  59  63
```

**Figure 33. Embedded Page Table Configuration Register**

### 6.10.3.5 LRAT Configuration Register (LRATCFG) [Category: Embedded.Hypervisor.LRAT]

The LRATCFG read-only register provides configuration information about the LRAT array. LRATCFG is a hypervisor resource. The layout of the LRATCFG registers is shown in Figure 34.

```
   ASSOC  LASIZE  //  LPID  /  NENTRY
   32  40  47  50  51  52  63
```

</tr>
</tbody>
</table>

All other fields are reserved.

### 6.10.3.6 LRAT Page Size Register (LRATPS) [Category: Embedded.Hypervisor.LRAT]

LRATPS is a read-only register that provides page size information about the LRAT that is implemented if the Embedded.Hypervisor.LRAT category is supported in MMU Architecture Version 2.0. Each Page Size bit (PS0-PS31) that is a one indicates that a specific logical page size is supported by the array. Multiple 1 bits indicate that multiple page sizes are supported concurrently. LRATPS is a hypervisor resource. The layout of the LRATPS registers is shown in Figure 35.

```
   PS31 - PS0
   32  63
```

**Figure 35. LRAT Page Size Register**

The LRATPS fields are described below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:63</td>
<td><strong>Page Size 31 - Page Size 0 (PS31-PS0)</strong></td>
</tr>
<tr>
<td></td>
<td>PSm indicates whether a logical page size of $2^m$ KB is supported by the LRAT array. PSm corresponds to bit LRATPS_{64-m} for m = 0 to 31.</td>
</tr>
<tr>
<td></td>
<td>0 Logical page size of $2^m$ KB is not supported.</td>
</tr>
<tr>
<td></td>
<td>1 Logical page size of $2^m$ KB is supported.</td>
</tr>
</tbody>
</table>

All other fields are reserved.
Table 9 on page 1106 shows the relationship between the Page Size (PSm) bits in LRATPS and the logical page size.

6.10.3.7 MMU Control and Status Register (MMUCSR0)

The MMUCSR0 register is used for general control of the MMU including page sizes for programmable fixed size TLB arrays [MAV=1.0] and invalidation of the TLB array. For TLB arrays that have programmable fixed sizes, the TLBn_PS fields [MAV=1.0] allow software to specify the page size. MMUCSR0 is a privileged register except that if the Embedded.Hypervisor category is supported, MMUCSR0 is a hypervisor resource.

The layout of the MMUCSR0 is shown in Figure 36 for MAV=1.0 and in Figure 37 for MAV=2.0.

### Programming Note
Changing the fixed page size of an entire array must be done with great care. If any entries in the array are valid, changing the page size may cause those entries to overlap, creating a serious programming error. It is suggested that the entire TLB array be invalidated and any entries with IPROT have their V bits set to zero before changing page size.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>41:44 TLB3 Array Page Size (TLB3_PS)</td>
<td>Page size of the TLB3 array.</td>

<td>Page size of the TLB2 array.</td>
</tr>
<tr>
<td>49:52 TLB1 Array Page Size (TLB1_PS)</td>
<td>Page size of the TLB1 array.</td>
</tr>
<tr>
<td>53:56 TLB0 Array Page Size (TLB0_PS)</td>
<td>Page size of the TLB0 array.</td>
</tr>
</tbody>
</table>

#### Bit Description

- **41:44 TLB3 Array Page Size (TLB3_PS)**
  - A 4-bit field specifies the page size for TLBn array. Page size encoding is defined in Section 6.7.2. If the value of TLBn_PS is not between TLBnCFG_MINSIZE and TLBnCFG_MAXSIZE, the page size is set to TLBnCFG_MINSIZE. A TLBn_PS field is implemented only for a TLB array that can be programmed to support only one of several fixed page sizes. For each TLB array n (for 0 ≤ n < MMUCFG_NTBLS), this field is implemented only if the following are all true.
    - TLBnCFG_AVAIL = 0.
    - TLBnCFG_MINSIZE ≠ TLBnCFG_MAXSIZE.

- **57:62 TLBn Invalidate All**
  - TLB invalidate all bit for the TLBn array.
    - 0 If this bit reads as a 1, an invalidate all operation for the TLBn array is in progress. Hardware will set this bit to 0 when the invalidate all operation is completed. Writing a 0 to this bit during an invalidate all operation is ignored.
    - 1 TLBn invalidation operation. Hardware initiates a TLBn invalidate all operation. When this operation is complete, this bit is cleared. Writing a 1 during an invalidate all operation produces an undefined result. If the TLB array supports IPROT, entries that have IPROT set will not be invalidated.

- **57 TLB2 Invalidate All (TLB2_FI)**
  - TLB invalidate all bit for the TLB2 array.
- **58 TLB3 Invalidate All (TLB3_FI)**
  - TLB invalidate all bit for the TLB3 array.
- **61 TLB0 Invalidate All (TLB0_FI)**
  - TLB invalidate all bit for the TLB0 array.
- **62 TLB1 Invalidate All (TLB1_FI)**
  - TLB invalidate all bit for the TLB1 array.

All other fields are reserved.

6.10.3.8 MAS0 Register

The MAS0 register contains fields for identifying and selecting a TLB entry. If the Embedded.Hypervisor.LRAT category is supported, the MAS0 register is also used to select an LRAT entry as well as select between a TLB array and the LRAT array. MAS0 register fields are loaded by the execution of the `tlbsx` instruction and by the occurrence of an Instruction or Data TLB Error interrupt under certain conditions.
MAS0 is a privileged register. The layout of the MAS0 register is shown in Figure 38.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>Array Type Select (ATSEL) [Category: Embedded.Hypervisor.LRAT]</td>
</tr>
<tr>
<td>33</td>
<td>Selects LRAT or TLB for access for tlbwe and tlbre. In guest state, MAS0ATSEL is treated as if it were zero such that a TLB array is always selected.</td>
</tr>
<tr>
<td>34</td>
<td>TLB Select (TLBSEL)</td>
</tr>
<tr>
<td>35</td>
<td>If ATSEL=0 or MSRGS=1, selects TLB for access. If ATSEL=1, TLBSEL is treated as reserved.</td>
</tr>
<tr>
<td>36</td>
<td>Entry Select (ESEL)</td>
</tr>
<tr>
<td>48</td>
<td>Identifies an entry in the selected array to be used for tlbwe and tlbre. Valid values for ESEL are from 0 to TLBnCFGASSOC - 1 for a TLB array and 0 to LRATCFGASSOC - 1 for the LRAT. That is, ESEL selects the entry in the selected array from the set of entries which can be used for translating addresses with the EPN (if TLBnCFG HES=0 and either MAS0ATSEL=0 or MSRGS=1), the combination of EPN, SIZE, and PID (for tlbwe if TLBnCFG HES=1, and either MAS0ATSEL=0 or MSRGS=1, and for tlbre if TLBnCFG HES=1, and either MAS0ATSEL=0 or MSRGS=0), or the LPN (if MAS0ATSEL=1 and MSRGS=0) specified by MAS2EPN. For fully-associative TLB or LRAT arrays, ESEL ranges from 0 to TLBnCFG NENTRY - 1 or 0 to LRATCFG NENTRY - 1, respectively.</td>
</tr>
<tr>
<td>49</td>
<td>Hardware Entry Select (HES) [MAV=2.0]</td>
</tr>
<tr>
<td>50</td>
<td>Determines how the TLB entry within the selected TLB array is selected by tlbwe if a TLB entry is to be written (MAS0ATSEL=0 or MSRGS=1). If an LRAT entry is to be written (MAS0ATSEL=1 and MSRGS=0) by a tlbwe, HES must be 0. Otherwise the result is undefined. This field has no effect on other TLB Management instructions. Whether an implementation supports this bit for a TLB array is indicated by TLBnCFG HES, and if TLBnCFG HES = 0, HES is ignored and treated as 0 for tlbwe.</td>
</tr>
<tr>
<td>51</td>
<td>Write Qualifier (WQ) [MAV=2.0 and Category: Embedded.TLB Write Conditional]</td>
</tr>
<tr>
<td>52</td>
<td>Qualifies the TLB write operation performed by tlbwe if a TLB entry is to be written (MAS0ATSEL=0 or MSRGS=1). If an LRAT entry is to be written (MAS0ATSEL=1 and MSRGS=0) by a tlbwe and the Embedded.TLB Write Conditional category is supported, WQ must be 0b00. Otherwise the result is undefined. This field has no effect on other TLB Management instructions. Whether an implementation supports this field is indicated by MMUCFGTW C. If MMUCFGTW C = 0, WQ is ignored and treated as 0b00 for tlbwe.</td>
</tr>
<tr>
<td>53</td>
<td>Next Victim (NV)</td>
</tr>
<tr>
<td>54</td>
<td>NV is a hint to software to identify the next victim to be targeted for a TLB miss replacement operation for those TLBs that support the NV function. If the TLB selected by MAS0TLBSEL does not support the NV function, this field is undefined. The method of determining the next victim is implementation-dependent. NV is updated on tlbx hit and miss cases as shown in Table 11 on page 1116, on execution of tlbre if the TLB array being accessed supports the NV field, and on TLB Error interrupts if the Embedded.Hypervisor category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCRDMIUH = 0), or the interrupt is directed to the guest state. When NV is updated by a supported TLB array, the NV field will always present a value that can be used in the MAS0ESEL field. The LRAT array does not support Next Victim.</td>
</tr>
</tbody>
</table>

All other fields are reserved.
### 6.10.3.9 MAS1 Register

The MAS1 register contains fields used for reading and writing an LRAT <E.HVL.RAT> or TLB entry. MAS1 register fields are also loaded by the execution of the `tlbxs` instruction and by the occurrence of an Instruction or Data TLB Error interrupt under certain conditions. TLB fields loaded from the MAS1 register are used for selecting a TLB entry during translation. If the Embedded.Hypervisor.LRAT category is supported, LRAT fields `V` and `LSIZE`, which are loaded from `MAS1V` and `TSIZE`, are used for selecting an LRAT entry for translating LPNs when `tlbwx` is executed in guest supervisor state and, if the Embedded.Page Table category is supported, during page table lookups performed when the `PTEREPN` is treated as an LPN (The Embedded.Hypervisor.LRAT category is supported and the TGS bit of the corresponding indirect TLB entry is 1). MAS1 is a privileged register. The layout of the MAS1 register is shown in Figure 39 for MAV=1.0 and in Figure 40 for MAV=2.0.

All other fields are reserved.

### 6.10.3.10 MAS2 Register

The MAS2 register is a 64-bit register which can be read and written as a 64-bit register in 64-bit implementations and as a 32-bit register in 32-bit implementations. In both 64-bit and 32-bit implementations, the MAS2 register contains fields used for reading and writing an LRAT <E.HVL.RAT> or TLB entry. MAS2 register fields are also loaded by the execution of the `tlbxs` instruction and by the occurrence of an Instruction or Data TLB Error interrupt under certain conditions. The register contains fields for specifying the effective page address and the storage control attributes for a TLB entry. If the Embedded.Hypervisor.LRAT category is supported, the MAS2 register EPN field can also be used for specifying the logical page number for an LRAT entry. The only MAS2 field used for the LRAT array is EPN. MAS2 is a privileged register. The layout of the MAS2 register is shown in Figure 41 for MAV=1.0 and in Figure 42 for MAV=2.0.

#### Figure 41. MAS2 register [MAV = 1.0]

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

All other fields are reserved.
tion in Section 6.9. Bits that correspond to an offset within the smallest virtual page implemented need not be implemented. Unimplemented EPN bits are treated as 0s.

57  **Alternate Coherency Mode (ACM)**
See the corresponding TLB bit definition in Section 6.7.1. If ACM is not supported by the implementation, this bit is treated as reserved.

58  **VLE Mode (VLE) [Category: VLE]**
See the corresponding TLB bit definition in Section 6.7.1. If the VLE category is not supported, this bit is treated as reserved.

---

**Programming Note**

Some previous implementations may have a TLB storage bit accessed via this bit position and labeled as X0. Software should not use the presence of this bit (the ability to set to 1 and read a 1) to determine if the implementation supports the Alternate Coherency Mode.

58  **VLE Mode (VLE) [Category: VLE]**
See the corresponding TLB bit definition in Section 6.7.1. If the VLE category is not supported, this bit is treated as reserved.

---

**Programming Note**

Some previous implementations may have a TLB storage bit accessed via this position and labeled as X1. Software should not use the presence of this bit (the ability to set to 1 and read a 1) to determine if the implementation supports the VLE.

59  **Write Through (W)**
See the corresponding TLB bit definition in Section 6.7.1.

60  **Caching Inhibited (I)**
See the corresponding TLB bit definition in Section 6.7.1.

61  **Memory Coherence Required (M)**
See the corresponding TLB bit definition in Section 6.7.1.

62  **Guarded (G)**
See the corresponding TLB bit definition in Section 6.7.1.

63  **Endianness (E)**
See the corresponding TLB bit definition in Section 6.7.1.

All other fields are reserved.

### 6.10.3.11 MAS3 Register

The MAS3 register contains fields used for reading and writing an LRAT <E.HVL RAT> or TLB entry. MAS3 register fields are also loaded by the execution of the `tlbsx` instruction and by the occurrence of an Instruction or Data TLB Error interrupt under certain conditions. The MAS3 register contains fields for specifying the real page address, user defined attributes, and the permission attributes for a TLB entry. If the Embedded.Page Table category is supported, MAS3 also contains a field specifying the minimum page size specified by each Page Table Entry that is mapped by the indirect TLB entry. If the Embedded.Hypervisor.LRAT category is supported, the low-order LRPN bits of the LRAT array can be read into or written from MAS3.RPNL by hypervisor software. If the Embedded.Hypervisor.LRAT category is supported, the RPN specified by MAS7 and MAS3 is treated as an LPN for `tlbwe` executed in guest supervisor state (see Section 6.9). MAS3 is a privileged register. If the Embedded.Page Table category is supported, MAS3 has different meanings depending on the MAS1IND value. For MAS1IND = 0, the layout of the MAS3 register is shown in Figure 43 for MAV=1.0 and in Figure 44 for MAV=2.0.

**Figure 43. MAS3 register for MAS1IND=0 [MAV=1.0]**

**Figure 44. MAS3 register for MAS1IND=0 [MAV=2.0]**

For MAS1IND = 1, the layout of the MAS3 register is shown in Figure 45.

---

**Figure 45. MAS3 register for MAS1IND=1 [MAV=2.0 and Category: E.PT]**

The MAS3 fields are described below.

**Bit Description**

32:51  **Real Page Number (bits 32:51)** (RPNL or RPN32:51) [MAV=1.0]
The real page number is formed by the upper n bits of (MAS7.RPNL || MAS3.RPNL), where n = 64 - log<sub>2</sub>(page size in bytes) and page size is specified by MAS1.TSIZE for a `tlbwe` instruction and by the SIZE field of the TLB entry if a TLB entry is being read by a `tlbre` or `tlbsx` instruction. RPN32:31 are accessed through MAS7. RPNL bits corresponding to bits that are not implemented in the RPN field of the TLB are treated as reserved.

32:53  **Real Page Number (bits 32:53)** (RPNL or RPN32:53) [MAV=2.0]
The real page number is formed by the upper n bits of (MAS7.RPNL || MAS3.RPNL), where n = 64 - log<sub>2</sub>(page size in bytes) and page size is...
specified by MAS1\textsubscript{TSIZE} for a \textit{tlbwe} instruction, by the \textit{SIZE} field of the TLB entry if a TLB entry is being read by a \textit{tlbre} or \textit{tlbsx} instruction or by the LSIZE field of the LRAT entry if an LRAT entry is being read by a \textit{tlbre} instruction. RPNL bits corresponding to bits that are not implemented in the RPN field of the TLB are treated as reserved.

54:57 \textbf{User Bits} (U0:U3)
See the corresponding TLB bit definition in Section 6.7.1. If one or more of these bits is not implemented in the TLB, the corresponding MAS3 bit is treated as reserved.

If MAS1\textsubscript{IND} = 0, MAS3\textsubscript{58:63} are defined as follows:

58 \textbf{User State Execute Enable (UX)}
See the corresponding TLB bit definition in Section 6.7.1.

59 \textbf{Supervisor State Execute Enable (SX)}
See the corresponding TLB bit definition in Section 6.7.1.

60 \textbf{User State Write Enable (UW)}
See the corresponding TLB bit definition in Section 6.7.1.

61 \textbf{Supervisor State Write Enable (SW)}
See the corresponding TLB bit definition in Section 6.7.1.

62 \textbf{User State Read Enable (UR)}
See the corresponding TLB bit definition in Section 6.7.1.

63 \textbf{Supervisor State Read Enable (SR)}
See the corresponding TLB bit definition in Section 6.7.1.

If MAS1\textsubscript{IND} = 1, MAS3\textsubscript{58:63} are defined as follows:

58:62 \textbf{Sub-Page Size (SPSIZE)}
See the corresponding TLB field definition in Section 6.7.1.

63 \textbf{Undefined} (UND)
The value of this bit is undefined after a \textit{tlbre} or \textit{tlbsx}.

All other fields are reserved.

6.10.3.12 MAS4 Register
The MAS4 register contains fields for specifying default information to be pre-loaded on an Instruction or Data TLB Error interrupt if the Embedded Hypervisor category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCR\textsubscript{DMUH} = 0), or the interrupt is directed to the guest state. See Section 6.11.4.7 for more information. MAS4 is a privileged register. The layout of the MAS4 register is shown in Figure 46 for MAV=1.0 and in Figure 47 for MAV=2.0.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure46.png}
\caption{MAS4 register [MAV=1.0]}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure47.png}
\caption{MAS4 register [MAV=2.0]}
\end{figure}

The MAS4 fields are described below.

\begin{itemize}
\item \textbf{Bit Description}
\item 34:35 \textit{TLBSEL Default Value} (TLBSELD) Specifies the default value loaded in MAS0\textsubscript{TLBSEL} on the interrupt.
\item 48 \textit{IND Default Value} (INDD) Specifies the default value loaded in MAS1\textsubscript{IND} and MAS6\textsubscript{SIND} on the interrupt.
\item 52:55 \textit{Default TSIZE Value} (TSIZED) \textbf{[MAV=1.0]} Specifies the default value loaded into MAS1\textsubscript{TSIZE} on a TLB miss exception.
\item 52:56 \textit{Default TSIZE Value} (TSIZED) \textbf{[MAV=2.0]} Specifies the default value loaded into MAS1\textsubscript{TSIZE} on a TLB miss exception. If MMUCFG\textsubscript{TWC} = 1, TSIZED is also the default value loaded into MAS6\textsubscript{ISIZE} on the interrupt.
\item 57 \textit{Default ACM Value} (ACMD) Specifies the default value loaded into MAS2\textsubscript{ACM} on the interrupt.
\item 58 \textit{Default VLE Value} (VLED) \textbf{[Category: VLE]} Specifies the default value loaded into MAS2\textsubscript{VLE} on the interrupt.
\item 59 \textit{Default W Value} (WD) Specifies the default value loaded into MAS2\textsubscript{W} on the interrupt.
\item 60 \textit{Default I Value} (ID) Specifies the default value loaded into MAS2\textsubscript{I} on the interrupt.
\item 61 \textit{Default M Value} (MD) Specifies the default value loaded into MAS2\textsubscript{M} on the interrupt.
\item 62 \textit{Default G Value} (GD) Specifies the default value loaded into MAS2\textsubscript{G} on the interrupt.
\end{itemize}
63  **Default E Value** (ED)
    Specifies the default value loaded into MAS2E on the interrupt.

All other fields are reserved.

### 6.10.3.13 MAS5 Register

The MAS5 register contains fields for specifying LPID and GS values to be used when searching TLB entries with the `tlbsrx`, `<E.TWC>` and `tlbsx` instructions. The SLPID and SGS fields are used to match TLPID and TGS fields in the TLB entry. The MAS5 fields are also used for selecting TLB entries to be invalidated by the `tlbilx` or `tlbivax` instructions. MAS5 is a hypervisor resource. The layout of the MA5 register is shown in Figure 48.

#### Figure 48. MAS5 register

The MAS5 fields are described below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td><strong>Search GS</strong> (SGS)</td>
</tr>
<tr>
<td>Specifies the GS value used when searching the TLB during execution of <code>tlbsrx</code>, <code>&lt;E.TWC&gt;</code> and <code>tlbsx</code> and for selecting TLB entries to be invalidated by <code>tlbilx</code> or <code>tlbivax</code>. The SGS field is compared with the TGS field of each TLB entry to find a matching entry.</td>
<td></td>
</tr>
</tbody>
</table>

| 52:63 | **Search Logical Partition ID** (SLPID) |
| Specifies the LPID value used when searching the TLB during execution of `tlbsrx`, `<E.TWC>` and `tlbsx` and for selecting TLB entries to be invalidated by `tlbilx` or `tlbivax`. The SLPID field is compared with the TLPID field of each TLB entry to find a matching entry. Only the least significant MMUCFG.LPID.SIZE bits of SLPID are implemented. |

All other fields are reserved.

#### Programming Note

Hypervisor software should generally treat MAS5 as part of the partition state.

### 6.10.3.14 MAS6 Register

The MAS6 register contains fields for specifying PID, IND, and AS values to be used when searching TLB entries with the `tlbsx` instruction and, if MMUCFG.TWC = 1 or TLBnCFG.HES = 1, for specifying the PID, IND, AS, and size of the virtual address space to be used for selecting TLB entries to be invalidated by the `tlbilx` T=3 or `tlbivax` instructions. MAS6 is a privileged register.

#### Figure 49. MAS6 register [MAV = 1.0]

The layout of the MAS6 register is shown in Figure 49 for MAV=1.0 and in Figure 50 for MAV=2.0.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td><strong>Search PID</strong> (SPID)</td>
</tr>
<tr>
<td>Specifies the value of PID used when searching the TLB during execution of <code>tlbsx</code> and for selecting TLB entries to be invalidated by <code>tlbilx</code> T=1 or T=3 and <code>tlbivax</code> with EA61=0. The number of bits implemented is the same as the number of bits implemented in the PID register.</td>
<td></td>
</tr>
</tbody>
</table>

| 52:56 | **Invalidation Size** (ISIZE) [MAV=2.0] |
| ISIZE defines the size of the virtual address space mapped by the TLB entry to be invalidated by `tlbilx` T=3 and `tlbivax`. This field is only supported if MMUCFG.TWC = 1 or, for any TLB array, TLBnCFG.HES = 1. Otherwise this field is reserved. |

| 62 | **Indirect Value for Searches** (SIND) [MAV=2.0 and Category: Embedded.Page Table] |
| Specifies the value of IND used when searching the TLB during execution of `tlbsx`. It also defines the Indirect (IND) value of the TLB entry to be invalidated by `tlbilx` T=3 and `tlbivax`. |

| 63 | **Address Space Value for Searches** (SAS) |
| Specifies the value of AS used when searching the TLB during execution of `tlbsx`. It also defines the TS value of the TLB entry to be invalidated by `tlbilx` T=3 and `tlbivax`. |

All other fields are reserved.
6.10.3.15 MAS7 Register

The MAS7 register contains a field used for reading and writing an LRAT <E.HV.LRAT> or TLB entry. MAS7 register field is also loaded by the execution of the `tlbsx` instruction. The MAS7 register contains the high order address bits of the RPN for a TLB entry in implementations that support more than 32 bits of physical address. If the Embedded.Hypervisor.LRAT category is supported by such implementations, the high-order LRPN bits of the LRAT array can be read into or written from MAS7 by hypervisor software. If the Embedded.Hypervisor.LRAT category is supported, the RPN specified by MAS7 and MAS3 is treated as an LPN for `tlbwe` executed in guest supervisor state (see Section 6.9). If no more than 32 bits of physical addressing are supported, it is implementation-dependent whether MAS7 is implemented. MAS7 is a privileged register. The layout of the MAS7 is shown in Figure 51.

Figure 51. MAS7 register

The MAS7 fields are described below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:63</td>
<td>Real Page Number (bits 0:31) (RPNU or RPN0:31)</td>
</tr>
<tr>
<td>32</td>
<td>Translation Guest State (TGS)</td>
</tr>
</tbody>
</table>

6.10.3.16 MAS8 Register [Category: Embedded.Hypervisor]

The MAS8 register contains fields used for reading and writing an LRAT <E.HV.LRAT> or TLB entry. The MAS8 register fields are also loaded from a matching TLB entry by execution of a `tlbsx` instruction that is successful. The associated TLB fields are used to select a TLB entry during TLB address translation and TLB searches, and to force a Data Storage Interrupt to be directed to the hypervisor state. MAS8 is a hypervisor resource. The LPID field of the LRAT is used to select an LRAT entry during LRAT translation. The layout of the MAS8 register is shown in Figure 52.

Figure 52. MAS8 register

The MAS8 fields are described below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>Translation Guest State (TGS)</td>
</tr>
</tbody>
</table>

6.10.3.17 Accesses to Paired MAS Registers

In 64-bit implementations, certain MAS registers can be accessed in pairs with a single `mtspr` or `mfspr` instruction. The registers that can be accessed this way are shown in Table 10. These register pairs are treated as if they are a single 64-bit register by a `mtspr` or `mfspr` instruction.

Table 10: MAS Register Pairs

<table>
<thead>
<tr>
<th>64-bit Pairs</th>
<th>SPR Number</th>
<th>Privileged <code>mtspr</code> &amp; <code>mfspr</code></th>
<th>Cat2</th>
</tr>
</thead>
<tbody>
<tr>
<td>MASS II MAS6</td>
<td>348</td>
<td>hypv&lt;sup&gt;1&lt;/sup&gt;</td>
<td>E.HV; 64</td>
</tr>
<tr>
<td>MASS II MAS1</td>
<td>349</td>
<td>hypv&lt;sup&gt;1&lt;/sup&gt;</td>
<td>E.HV; 64</td>
</tr>
<tr>
<td>MASS7 II MAS3</td>
<td>372</td>
<td>yes</td>
<td>64</td>
</tr>
<tr>
<td>MASS0 II MAS1</td>
<td>373</td>
<td>yes</td>
<td>64</td>
</tr>
</tbody>
</table>

1 This register is a hypervisor resource, and can be accessed by one of these instructions only in hypervisor state (see Chapter 2).
2 See Section 1.3.5 of Book I. If multiple categories are listed, the register pair is only provided if all categories are supported. Otherwise the SPR number is treated as reserved.

Programming Note

Hypervisor software should generally treat MAS8 as part of the partition state. After executing `tlbsx` and `tlbre`, hypervisor software may need to restore MAS8 before returning to guest state. This is especially important if the Embedded.Hypervisor.LRAT category is supported because a guest can execute a `tlbwe` instruction that writes a TLB entry with the MAS8 values.

Programming Note

For a TLB entry with VF=1, hypervisor software should have the execution permission bits set so that an instruction fetch of the page is prevented.

The VF bit can be used to force a Data Storage interrupt for virtualization of MMIO.
6.10.3.18 MAS Register Update Summary

Table 11 summarizes how MAS registers are modified by Instruction TLB Error interrupt, Data TLB Error interrupt and the TLB Management instructions.
### Table 11: MAS Register Update Summary for TLB operations

</table>

1. If MSR_CM=0 (32-bit mode) at the time of the exception, EPN0:31 are set to 0.
2. If the E.HV category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCRDMIUH = 0), or the interrupt is directed to the guest state.
3. MAS5 and MAS8 are not updated on a Data or Instruction TLB Error interrupt. The hypervisor should ensure they already contain values appropriate to the partition.
6.11 Storage Control Instructions

6.11.1 Cache Management Instructions

This section describes aspects of cache management that are relevant only to privileged software programmers.

For a `dcbz` or `dcba` instruction that causes the target block to be newly established in the data cache without being fetched from main storage, the hardware need not verify that the associated real address is valid. The existence of a data cache block that is associated with an invalid real address (see Section 6.6) can cause a delayed Machine Check interrupt or a delayed Check-stop.

Each implementation provides an efficient means by which software can ensure that all blocks that are considered to be modified in the data cache have been copied to main storage before the thread enters any power conserving mode in which data cache contents are not retained.

**Data Cache Block Invalidate X-form**

```
dcbi RA,RB
```

if RA=0 then b ← 0
else         b ← (RA)
EA ← b + (RB)
InvalidateDataCacheBlock( EA )

Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any thread, then the block is invalidated in those data caches. On some implementations, before the block is invalidated, if any locations in the block are considered to be modified in any such data cache, those locations are written to main storage and additional locations in the block may be written to main storage.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of this thread, then the block is invalidated in that data cache. On some implementations, before the block is invalidated, if any locations in the block are considered to be modified in that data cache, those locations are written to main storage and additional locations in the block may be written to main storage.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a Store (see Section 6.7.6.5) on implementations that invalidate a block without first writing to main storage all locations in the block that are considered to be modified in the data cache, except that the invalidation is not ordered by `mbar`. On other implementations this instruction is treated as a Load (see the section cited above).

If a thread holds a reservation and some other thread executes a `dcbi` that specifies a location in the same reservation granule, the reservation may be lost only if the `dcbi` is treated as a Store.

`dcbi` may cause a cache locking exception, the details of which are implementation-dependent.

This instruction is privileged.

**Special Registers Altered:**

None
6.11.2 Cache Locking [Category: Embedded Cache Locking]

The Embedded Cache Locking category defines instructions and methods for locking cache blocks for frequently used instructions and data. Cache locking allows software to instruct the cache to keep latency sensitive data readily available for fast access. This is accomplished by marking individual cache blocks as locked.

A locked block differs from a normal block in the cache in the following way:
- Blocks that are locked in the cache do not participate in the normal replacement policy when a block must be replaced.

6.11.2.1 Lock Setting, Query, and Clearing

Cache Locking instructions are used by software to indicate which blocks in a cache should be locked, unlocked, or queried for lock status.

Blocks are locked into the cache by software using Lock Set instructions. The following instructions are provided to lock data items into the data and instruction cache:
- `dcbls` - Data cache block touch and lock set.
- `dcbstls` - Data cache block touch for store and lock set.
- `icbls` - Instruction cache block touch and lock set.

The RA and RB operands in these instructions are used to identify the block to be locked. The CT field indicates which cache in the cache hierarchy should be targeted. These instructions set CR0 to indicate whether the block is locked or is not locked.

The status of whether a cache block is locked in the cache can be queried by software using Lock Query instructions:
- `dcblq` - Data cache block lock query.
- `icblq` - Instruction cache block lock query.

The RA and RB operands in these instructions are used to identify the block to be queried. The CT field indicates which cache in the cache hierarchy should be targeted. These instructions set CR0 to indicate whether the block is locked or is not locked.

An implementation is not required to unlock blocks that contain data that has been invalidated unless it is explicitly unlocked with a `dcblc` or `icblc` instruction; if the implementation does not unlock the block upon invalidation, the block remains locked even though it contains invalid data. If the implementation does not clear locks when the associated block is invalidated, the method of locking is said to be persistent; otherwise it is not persistent. An implementation may choose to implement locks as persistent or not persistent; however, the preferred method is persistent.

It is implementation-dependent if cache blocks are implicitly unlocked in the following ways:
- A locked block is invalidated as the result of a `dcbi`, `dcbf`, `dcbls`, `icbls`, or `icblc` instruction.
- A locked block is evicted because of an overlocking condition.
- A snoop hit on a locked block that requires the block to be invalidated. This can occur because the data the block contains has been modified external to the thread, or another thread has explicitly invalidated the block.
- The entire cache containing the locked block is invalidated.

6.11.2.2 Error Conditions

Setting locks in the cache can fail for a variety of reasons. A Lock Set instruction addressing a byte in storage that is not allowed to be accessed by the storage access control mechanism (see Section 6.7.6) will cause a Data Storage interrupt (DSI). Addresses referenced by Cache Locking instructions are always translated as data references; therefore, `icblts` instructions that fail to translate or are not allowed by the storage access control mechanism cause Data TLB Error interrupts and Data Storage interrupts, respectively. Cache Locking and clearing operations can fail due to non-privileged access. The methods for determining other failure conditions such as unable-to-lock or overlocking (see below), is implementation-dependent.

If the Embedded.Hypervisor category is supported and MSRPUCLEP = 1, an attempt to execute a Cache Locking instruction in guest state results in an Embedded Hypervisor Privilege exception if MSRPR = 0 or a cache...
locking exception if \( \text{MSR}_{\text{PR}} = 1 \). When the Embedded.Hypervisor category is not supported, \( \text{MSR}_{\text{PUCLEP}} = 0 \), or \( \text{MSR}_{\text{GS}} = 0 \), then if a Cache Locking instruction is executed in user mode and \( \text{MSR}_{\text{UCLE}} = 0 \), a cache locking exception occurs. If a Data Storage interrupt occurs as a result of a cache locking exception, one of the following ESR or GESR bits is set to 1 (GESR if the Embedded.Hypervisor category is supported and the interrupt is directed to the guest. Otherwise, ESR).

The behavior of Cache Locking instructions in guest privileged state (\textit{dcbtls}, \textit{dcbtstsl}, \textit{dcblc}, \textit{dcblq}, \textit{icbtls}, \textit{icblc}, \textit{icblq}) is dependent on the setting of \( \text{MSR}_{\text{PUCLEP}} \). When \( \text{MSR}_{\text{PUCLEP}} = 0 \), Cache Locking instructions are permitted to execute normally in the guest privileged state. When \( \text{MSR}_{\text{PUCLEP}} = 1 \), cache locking instructions are not permitted to execute in the guest privileged state and cause an Embedded Hypervisor Privilege exception when executed. See Section 4.2.2, “Machine State Register Protect Register (MSRP)”.

6.11.2.2.1 Overlocking

If no exceptions occur for the execution of an \textit{dcbtls}, \textit{dcbtstsl}, or \textit{icbtls} instruction, an attempt is made to lock the specified block into the cache. If all of the available cache blocks into which the specified block may be loaded are already locked, an overlocking condition occurs. The overlocking condition may be reported in an implementation-dependent manner.

If an overlocking condition occurs, it is implementation-dependent whether the specified block is not locked into the cache or if another locked block is evicted and the specified block is locked.

The selection of which block is replaced in an overlocking situation is implementation-dependent. The overlocking condition is still said to exist, and is reflected in any implementation-dependent overlocking status.

An attempt to lock a block that is already present and valid in the cache will not cause an overlocking condition.

If a cache block is to be loaded because of an instruction other than a Cache Management or Cache Locking instruction and all available blocks into which the block can be loaded are locked, the instruction executes and completes, but no cache blocks are unlocked and the block is not loaded into the cache.

---

**Programming Note**

Since caches may be shared among threads, an overlocking condition may occur when loading a block even though a given thread has not locked all the available cache blocks. Similarly, blocks may be unlocked as a result of invalidations by other threads.

6.11.2.2.2 Unable-to-lock, Unable-to-unlock, and Unable-to-query Conditions

If no exceptions occur and no overlocking condition exists, an attempt to set, query, or unlock a lock may fail if any of the following are true:

- The target address is marked Caching Inhibited, or the storage control attributes of the address use a coherency protocol that does not support locking.
- The target cache is disabled or not present.
- The CT field of the instructions contains a value not supported by the implementation.
- Any other implementation-specific error conditions are detected.

If an unable-to-lock or unable-to-unlock condition occurs, the Lock Set or Lock Clear instruction is treated as a no-op and the condition may be reported in an implementation-dependent manner. If an unable-to-query condition occurs, the CR0 status bit for the query is set to 0.
6.11.2.3 Cache Locking Instructions

**Data Cache Block Lock Query X-form**

```
dcblq        CT,RA,RB
```

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 |
|-----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| 0   | /  | CT | RA | RB | 422 | 1 |

Let the effective address (EA) be the sum (RA0)+(RB).
The block containing the byte addressed by EA in the
data cache specified by the CT field is queried to deter-
mine its lock status and CR0 is set as follows:

\[
\text{CR0} = 0b00 \parallel \text{status} \parallel \text{XERSO}
\]

Status is set to 1 if the block is locked in the data cache
specified by the CT field. Status is set to 0 if the block is
not locked in the data cache specified by the CT field.
The instruction is treated as a *Load*.

If an unable-to-query condition occurs (see Section 6.11.2.2.2) status is set to 0.

This instruction is privileged unless the Embedded
Cache Locking,User Mode category is supported. If the
Embedded Cache Locking,User Mode category is sup-
ported, this instruction is privileged only if MSR\textsubscript{UCLE}=0.

**Special Registers Altered:**

CR0

**Instruction Cache Block Lock Query X-form**

```
icblq        CT,RA,RB
```

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 |
|-----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| 0   | /  | CT | RA | RB | 198 | 1 |

Let the effective address (EA) be the sum (RA0)+(RB).
The block containing the byte addressed by EA in the
instruction cache specified by the CT field is queried to
determine its lock status and CR0 is set as follows:

\[
\text{CR0} = 0b00 \parallel \text{status} \parallel \text{XERSO}
\]

Status is set to 1 if the block is locked in the instruction
cache specified by the CT field. Status is set to 0 if the
block is not locked in the instruction cache specified by
the CT field.
The instruction is treated as a *Load*.

If an unable-to-query condition occurs (see Section 6.11.2.2.2) status is set to 0.

This instruction is privileged unless the Embedded
Cache Locking,User Mode category is supported. If the
Embedded Cache Locking,User Mode category is sup-
ported, this instruction is privileged only if MSR\textsubscript{UCLE}=0.

**Special Registers Altered:**

CR0
**Data Cache Block Touch and Lock Set**

**X-form**

<table>
<thead>
<tr>
<th>dcbtls</th>
<th>CT, RA, RB</th>
</tr>

<td>11</td>
<td>RB</td>
</tr>
<tr>
<td>16</td>
<td>21</td>
</tr>
<tr>
<td>166</td>
<td>/ 31</td>
</tr>
</tbody>
</table>

Let the effective address (EA) be the sum (RA0)+(RB).

The `dcbtls` instruction provides a hint that the program will probably soon load from the block containing the byte addressed by EA, and that the block containing the byte addressed by EA is to be loaded and locked into the cache specified by the CT field. (See Section 4.3 of Book II.) If the CT field is set to a value not supported by the implementation, no operation is performed.

If the block already exists in the cache, the block is locked without accessing storage. An unable-to-lock condition may occur (see Section 6.11.2.2.2), or an overlocking condition may occur (see Section 6.11.2.2.1).

The `dcbtls` instruction may complete before the operation it causes has been performed.

The instruction is treated as a *Load*.

This instruction is privileged unless the Embedded Cache Locking.User Mode category is supported. If the Embedded Cache Locking.User Mode category is supported, this instruction is privileged only if MSR\textsubscript{UCLE}=0.

**Special Registers Altered:**

None

---

**Data Cache Block Touch for Store and Lock Set**

**X-form**

<table>
<thead>
<tr>
<th>dcbtstls</th>
<th>CT, RA, RB</th>
</tr>

<tr>
<td>11</td>
<td>RB</td>
</tr>
<tr>
<td>16</td>
<td>21</td>
</tr>
<tr>
<td>134</td>
<td>/ 31</td>
</tr>
</tbody>
</table>

Let the effective address (EA) be the sum (RA0)+(RB).

The `dcbtstls` instruction provides a hint that the program will probably soon store to the block containing the byte addressed by EA, and that the block containing the byte addressed by EA is to be loaded and locked into the cache specified by the CT field. (See Section 4.3 of Book II.) If the CT field is set to a value not supported by the implementation, no operation is performed.

If the block already exists in the cache, the block is locked without accessing storage. An unable-to-lock condition may occur (see Section 6.11.2.2.2), or an overlocking condition may occur (see Section 6.11.2.2.1).

The `dcbtstls` instruction may complete before the operation it causes has been performed.

The instruction is treated as a *Store*.

This instruction is privileged unless the Embedded Cache Locking.User Mode category is supported. If the Embedded Cache Locking.User Mode category is supported, this instruction is privileged only if MSR\textsubscript{UCLE}=0.

**Special Registers Altered:**

None
**Instruction Cache Block Touch and Lock Set**

`icbtls CT,RA,RB`

Let the effective address (EA) be the sum (RA0)+(RB).

The `icbtls` instruction causes the block containing the byte addressed by EA to be loaded and locked into the instruction cache specified by CT, and provides a hint that the program will probably soon execute code from the block. See Section 4.3 of Book II for a definition of the CT field.

If the block already exists in the cache, the block is locked without refetching from memory.

This instruction treated as a Load (see Section 4.3 of Book II).

If an unable-to-lock condition occurs (see Section 6.11.2.2.2) no operation is performed.

This instruction is privileged unless the Embedded Cache Locking User Mode category is supported. If the Embedded Cache Locking User Mode category is supported, this instruction is privileged only if MSRUCLE=0.

**Special Registers Altered:**

None

**Instruction Cache Block Lock Clear**

`icblc CT,RA,RB`

Let the effective address (EA) be the sum (RA0)+(RB).

The block containing the byte addressed by EA in the instruction cache specified by the CT field is unlocked.

The instruction is treated as a Load.

If an unable-to-lock condition occurs (see Section 6.11.2.2.2) no operation is performed. If the block containing the byte addressed by EA is not locked in the specified cache, no cache operation is performed.

This instruction is privileged unless the Embedded Cache Locking User Mode category is supported. If the Embedded Cache Locking User Mode category is supported, this instruction is privileged only if MSRUCLE=0.

**Special Registers Altered:**

None

**Data Cache Block Lock Clear**

`dcblc CT,RA,RB`

Let the effective address (EA) be the sum (RA0)+(RB).

The block containing the byte addressed by EA in the data cache specified by the CT field is unlocked.

The instruction is treated as a Load.

If an unable-to-lock condition occurs (see Section 6.11.2.2.2) no operation is performed. If the block containing the byte addressed by EA is not locked in the specified cache, no cache operation is performed.

This instruction is privileged unless the Embedded Cache Locking User Mode category is supported. If the Embedded Cache Locking User Mode category is supported, this instruction is privileged only if MSRUCLE=0.

**Special Registers Altered:**

None

**Programming Note**

The `dcblc` and `icblc` instructions are used to remove locks previously set by the corresponding lock set instructions.
6.11.3 Synchronize Instruction

The Synchronize instruction is described in Section 4.4.3 of Book II, but only at the level required by an application programmer. This section describes properties of the instruction that are relevant only to operating system programmers.

When \( L=1 \), the Sync instruction provides an ordering function for the operations caused by the Message Send instruction and previous Stores for which the specified storage location is in storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited. The stores must be performed with respect to the thread receiving the message prior to any access caused by or associated with any instruction executed after the corresponding interrupt is taken.

In conjunction with the `tlbie` and `tlbsync` instructions, when \( L=0 \), the Sync instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the `tlbsync` instruction description on page 1141.

When \( L=0 \), the Sync instruction also provides an ordering function for the operations caused by the Message Send instruction and previous Stores. The stores must be performed with respect to the thread receiving the message prior to any access caused by or associated with any instruction executed after the corresponding interrupt is taken.

6.11.4 LRAT [Category: Embedded.Hypervisor.LRAT] and TLB Management

Unless the Embedded.Page Table category is supported, no format for the Page Tables or the Page Table Entries is implied. Software has significant flexibility in implementing a custom replacement strategy. For example, software may choose to set IPROT=1 for TLB entries that correspond to frequently used storage, so that those entries are never cast out of the TLB and TLB Miss exceptions to those pages never occur. At a minimum, software must maintain a TLB entry or entries for the Instruction and Data TLB Error interrupt handlers.

TLB management is performed in software with some hardware assist. This hardware assist consists of a minimum of:

- Automatic recording of the effective address causing a TLB Error interrupt. For Instruction TLB Error interrupts, the address is saved in the Save/Restore Register 0. For Data TLB Error interrupts, the address is saved in the Data Exception Address Register.

- Automatic updating of the MAS register on the occurrence of a TLB Error interrupt if the Embedded.Hypervisor category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCRDMUIH = 0), or the interrupt is directed to the guest state.

- Instructions for reading, writing, searching, invalidating, and synchronizing the TLB. If the Embedded.Hypervisor.LRAT category is supported, a subset of these instructions can also be used for reading and writing the LRAT.

  **Programming Note**

If the Embedded.Hypervisor category is supported and if EPCR_TLBGS DTLBGS = 0b00, the hypervisor can virtualize the physical TLB by keeping a software copy of at least the guest operating system TLB entries with IPROT=1 and avoid keeping the guest Instruction and Data TLB Error interrupt handlers in the physical TLB.

6.11.4.1 Reading TLB or LRAT Entries

TLB entries can be read by executing `tlbre` instructions. If the Embedded.Hypervisor.LRAT category is supported, LRAT entries can be read by also executing `tlb` instructions. At the time of `tlbre` execution, a TLB array is selected if \( \text{MAS0_ATSEL} = 0 \) or \( \text{MSRGS} = 1 \). The LRAT array is selected if \( \text{MAS0_ATSEL} = 1 \) and \( \text{MSRGS} = 0 \). The LRAT can be read only when in hypervisor state.

If a TLB array is selected, \( \text{MAS0TLBSEL} \) selects the TLB array to be read. If TLBnCFG_HES=0, the TLB entry in the selected TLB array is selected by \( \text{MAS0ESEL} \) and \( \text{MAS2_EPN} \). In this case, \( \text{MAS0ESEL} \) selects one of the possible entries that can be used for a given \( \text{MAS2_EPN} \). If TLBnCFG_HES=1, the TLB entry in the selected TLB array is selected by \( \text{MAS0ESEL} \) and by a hardware generated hash based on \( \text{MAS1_TID TSIZE} \) and \( \text{MAS2_EPN} \). In this case, \( \text{MAS0ESEL} \) selects one of the possible entries that can be used for a given \( \text{MAS1_TID TSIZE} \) and \( \text{MAS2_EPN} \).

If an LRAT array is selected, the LRAT entry is selected by \( \text{MAS0ESEL} \) and \( \text{MAS2_EPN} \). In this case, \( \text{MAS0ESEL} \) selects one of the possible entries that can be used for a given \( \text{MAS2_EPN} \).

Specifying invalid values for \( \text{MAS0TLBSEL} \), \( \text{MAS0ESEL} \), \( \text{MAS2_EPN} \) or, if TLBnCFG_HES=1, \( \text{MAS1_TID} \) or \( \text{MAS1_TSIZE} \), results in \( \text{MAS1y} \) being set to 0 and undefined results in the other MAS register fields that are loaded by the `tlbre` instruction. Which values are invalid is implementation-dependent. For example, even though an implementation has only one TLB array, the implementation could simply ignore \( \text{MAS0TLBSEL} \), read the selected entry in the TLB array, and load the MAS registers from the TLB entry regardless of the \( \text{MAS0TLBSEL} \) value.
6.11.4.2 Writing TLB or LRAT Entries

TLB entries can be written by executing `tlbwe` instructions. If the Embedded.Hypervisor.LRAT category is supported, LRAT entries can also be written by executing `tlbwe` instructions. At the time of `tlbwe` execution, a TLB array is selected if MAS0ATSEL=0 or MSRGS=1. The LRAT array is selected if MAS0ATSEL=1 and MSRGS=0. The LRAT can be written only when in hypervisor state.

If a TLB array is selected, MAS0TLBSEL selects the TLB array to be written. If TLBnCFGHES=0, the TLB entry in the selected TLB array is selected by MAS0ESEL and MAS2EPN. In this case, MAS0ESEL selects one of the possible entries that can be used for a given MAS2EPN. If TLBnCFGHES=1 and MAS0HES=0, the TLB entry in the selected TLB array is selected by a hardware generated hash based on MAS1TID TSIZE, MAS2EPN, and MAS0ESEL. In this case, MAS0ESEL selects one of the possible entries that can be used for a given MAS0TLSEL, MAS1TID TSIZE, and MAS2EPN. If TLBnCFGHES=1 and MAS0HES=1, the TLB entry in the selected TLB array is selected by a hardware replacement algorithm and a hardware generated hash based on MAS1TID TSIZE and MAS2EPN.

If an LRAT array is selected, the LRAT entry is selected by MAS0ESEL and MAS2EPN. In this case, MAS0ESEL selects one of the possible entries that can be used for a given MAS2EPN. LRAT entries can be written only with MAS0HES=0.

At the time of `tlbwe` execution, the MAS registers contain the contents to be written to the indexed TLB entry. Upon completion of the `tlbwe` instruction, the contents of the MAS registers corresponding to TLB entry fields will be written to the indexed TLB entry, except that if the Embedded.Hypervisor.LRAT category is supported, guest execution of `TLB MANAGEMENT` instructions is enabled (EPCR[GTMI]=0), MSRPR = 0, MSRGS = 1, and, for the TLB array to be written, TLBnCFGGTWE = 1, the RPN from the MAS registers is treated like an LPN and translated by the LRAT, and the RPN from the LRAT is written to the TLB entry if the translation is successful. See Section 6.9. If the LRAT translation fails, an LRAT Miss exception occurs.

If the Embedded.Hypervisor.LRAT category is supported and a guest supervisor executes a `tlbwe` instruction with IPROT=1 or for which the entry to be overwritten has IPROT=1, an Embedded Hypervisor Privilege exception occurs. However, if MAS0WO=0b01, it is implementation-dependent whether the Embedded Hypervisor Privilege exception occurs.

If the Embedded.Hypervisor.LRAT category is supported and a guest supervisor executes a `tlbwe` instruction with MAS0WO=0, it is implementation-dependent whether the Embedded Hypervisor Privilege exception occurs.

If a TLB entry is being written with MAS0HES=1, the hardware replacement algorithm picks an entry in the selected array from the set of entries which can be used for translating addresses with the specified TID, TSIZE and EPN. Whenever possible, an entry with IPROT equal to 0 is selected. However, an Embedded Hypervisor Privilege exception occurs on a `tlbwe` if all the following conditions are met.

- The Embedded.Hypervisor.LRAT category is supported.
- The `tlbwe` is executed in guest supervisor state.
- IPROT=1 for all entries which can be used for translating addresses with the specified TID, TSIZE and EPN.
- MAS0WO= 0b00

If MAS0WO= 0b01, MAS0HES =1, and the first three of the above conditions are met, it is implementation-dependent whether an Embedded Hypervisor Privilege exception occurs.

For TLBs with TLBnCFGHES=1, the relationship between the TLB entry selected by a `tlbwe` with MAS0HES=0 versus the TLB entry selected by a `tlbwe` with MAS0HES=1 is implementation-dependent and may depend on the history of TLB use.

If an invalid value is specified for MAS0TLBSEL, MAS0ESEL or MAS2EPN, either no TLB entry is written by the `tlbwe`, or the `tlbwe` is performed as if some implementation-dependent, valid value were substituted for the invalid value, or an Illegal Instruction exception occurs. If the page size specified by MAS1TSIZE is not supported by the specified array, the `tlbwe` may be performed as if TSIZE were some implementation-dependent value, or an Illegal Instruction exception occurs.

If the Embedded.Hypervisor category is supported but the Embedded.Hypervisor.LRAT category is not supported, the `tlbwe` instruction is hypervisor privileged. Otherwise, this instruction is privileged.

--- Programming Note ---

When reading TLB entries, MAS2EPN or a subset of the bits in MAS2EPN is used to form the index for accessing the TLB array, i.e. MAS2EPN isn’t necessarily an effective page number.

--- Programming Note ---

Since a hardware replacement algorithm selects the entry for a `tlbwe` instruction with MAS0HES =1, it is typically not possible to write the same entry using a second `tlbwe` instruction with MAS0HES =1. Doing so might create multiple entries for the same virtual page. If software needs to change the value of any of the TLB fields, software should generally invalidate the original entry before executing the second `tlbwe` instruction with the new values.
6.11.4.2.1 TLB Write Conditional [Embedded.TLB Write Conditional]

The \textit{tlbsrx}. \textit{<E.TWC>} instruction and \textit{tlbwe} instruction with \textit{MAS0\textsubscript{WO}} = 0b01 together permit a convenient way for software to write a TLB entry while ensuring that the entry is not a duplicate entry and is not a stale, invalid value. Without the TLB Write Conditional facility, software must hold a software lock during the process of creating a TLB entry in order to prevent other threads from updating a shared TLB or invalidating a TLB entry. The \textit{tlbsrx}. \textit{<E.TWC>} instruction has two effects that occur either at the same time or in the following order.

1. A TLB-reservation is established for a virtual address, and, if the Embedded Page Table category is supported, an associated IND value.

2. A search of the selected TLB array is performed. The TLB-reservation is used by a subsequent \textit{tlbwe} instruction that writes a TLB entry (i.e. \textit{MAS0\textsubscript{ATSEL}} = 0 or \textit{MSR\textsubscript{GS}}=1) with \textit{MAS0\textsubscript{WO}} = 0b01. The TLB is only written by this \textit{tlbwe} if the TLB-reservation still exists at the instant the TLB is written. A \textit{tlbwe} that writes the TLB is said to "succeed". TLB Write Conditional cannot be used for the LRAT.

\textbf{TLB-reservation}

A TLB-reservation is set by a \textit{tlbsrx}. \textit{<E.TWC>} instruction. The TLB-reservation has an associated IND \textit{<E.PT>} and virtual address consisting of AS, PID, EA\textsubscript{0:n-1}, LPID \textit{<E.HV>}, and GS \textit{<E.HV>}. These values come from \textit{MAS1\textsubscript{IND} \textit{<E.PT>}; MAS1\textsubscript{TS} MAS1\textsubscript{TID}; MAS2\textsubscript{EPN}; MAS5\textsubscript{SLPID} \textit{<E.HV>}, and MAS5\textsubscript{SGS} \textit{<E.HV>}, respectively. There is no specific page size associated with the TLB-reservation. The TLB-reservation applies to any virtual page that contains the virtual address. There is only one TLB-reservation in a thread.

The TLB-reservation is cleared by any of the following.

- The thread holding the TLB-reservation executes another \textit{tlbsrx}. \textit{<E.TWC>}: This clears the first TLB-reservation and establishes a new one.
- A \textit{tlbivax} is executed by any thread and all the following conditions are met.
  - Either the Embedded.Hypervisor category is not supported or the \textit{MAS0\textsubscript{SGS}} and \textit{MAS0\textsubscript{SLPID}} values used by the \textit{tlbivax} match the GS and LPID values associated with the TLB-reservation.
  - The \textit{MAS5\textsubscript{SLPID}} and \textit{MAS6\textsubscript{SAS}} values used by the \textit{tlbivax} match the GS, LPID, PID, and AS values associated with the TLB-reservation, and a \textit{tlbwe} with \textit{T} = 3 is executed by the thread holding the TLB-reservation.
  - The \textit{EA\textsubscript{0:n-1}} values of the \textit{tlbivax} match the \textit{EA\textsubscript{0:n-1}} values associated with the TLB-reservation, where \textit{n}=$64\cdot\log_2$\textit{(page size in bytes)} and \textit{page size} is specified by the \textit{MAS6\textsubscript{SIZE}}.

A \textit{tlbwe} instruction is executed by the thread holding the TLB-reservation or by a thread that shares the TLB with this thread, and all the following are true.

- An interrupt does not occur as a result of the \textit{tlbwe} instruction.
- The Embedded.Hypervisor category is not supported or the \textit{MAS8\textsubscript{TLPID}} value used by the \textit{tlbwe} matches the LPID value associated with the TLB-reservation.
- The Embedded.Hypervisor category is not supported or the \textit{MAS8\textsubscript{TGS}} value used by the \textit{tlbwe} matches the GS value associated with the TLB-reservation.
- The \textit{MAS1\textsubscript{TID}} value used by the \textit{tlbwe} matches the PID value associated with the TLB-reservation.
- The Embedded.Page Table category is not supported or the \textit{MAS1\textsubscript{IND}} value used by the \textit{tlbwe} matches the IND value associated with the TLB-reservation.
- The \textit{MAS1\textsubscript{TS}} value used by the \textit{tlbwe} matches the AS value associated with the TLB-reservation.
- \textit{Bits 0:(n-1)} of \textit{MAS2\textsubscript{EPN}} used by the \textit{tlbwe} match the \textit{EA\textsubscript{0:n-1}} values associated with the TLB-reservation, where \textit{n}=$64\cdot\log_2$\textit{(page size in bytes)} and \textit{page size} is specified by the \textit{MAS1\textsubscript{SIZE}} used by the \textit{tlbwe}.

Either of the following conditions are met.

- The \textit{MAS0\textsubscript{WO}} used by the \textit{tlbwe} instruction is 0b00.
The MAS0\textsubscript{WO} used by the `tlbwe` instruction is 0b01 and the TLB-reservation for the thread executing the `tlbwe` exists.

The thread that has the TLB-reservation or another thread that shares the TLB with this thread that, as a result of a Page Table translation, writes a TLB entry and all the following conditions are met.

- The TS and EA\textsubscript{0:n-1} values for the new TLB entry match the corresponding values associated with the TLB-reservation where n = 64-log\textsubscript{2}(\textit{page size in bytes}), where \textit{page size} is specified by the SIZE value written to the TLB entry.
- The Embedded.Hypervisor category is not supported or TLPID for the new TLB entry matches the LPID associated with the TLB-reservation.
- The Embedded.Hypervisor category is not supported or TGS for the new TLB entry matches the GS associated with the TLB-reservation.
- The TID for the new TLB entry matches the PID associated with the TLB-reservation.
- The Valid bit for the new TLB entry is 1.
- The IND value associated with the TLB-reservation is 0.

Implementations are allowed to clear a TLB-reservation for conditions other than those specified above. The architecture assures that a TLB-reservation will be cleared when required per the above requirements, but does not guarantee that these are the only conditions for clearing a TLB-reservation. However, the occurrence of an interrupt does not clear a TLB-reservation.

### Programming Note
Software running on two threads that share a TLB should not attempt to create two TLB entries that would both translate a specific virtual address and where the TID or LPID values differ, i.e. one of the values is zero and the other is nonzero. The TLB-reservation will not protect against this case, since a TLB-reservation is not cleared by a `tlbwe` unless there is an exact match on the PID and LPID values.

Likewise software should not attempt to create a Page Table entry and a TLB entry where both entries would translate a specific virtual address, where the TLB array written by the Page Table translation is used by the same thread that uses this TLB entry, and where the TID or LPID values of the PTE and TLB entry differ, i.e. one of the values is zero and the other is nonzero. The TLB-reservation will not protect against this case, since a TLB-reservation is not cleared by a TLB write resulting from a Page Table translation unless there is an exact match on the PID and LPID values.

## Synchronization of TLB-reservation
The side-effect of a `tlbsrx`. `<E.TWC>` instruction setting the TLB-reservation can be synchronized by a context synchronizing instruction or event.

### Programming Note
A common operation is to ensure that the TLB-reservation has been set by a `tlbsrx`. `<E.TWC>` instruction before executing a subsequent \textit{Load} instruction of a software page table entry in order to ensure the TLB-reservation detects an invalidation of the entry that was accessed. Beside using a context synchronizing instruction, software can also ensure the TLB-reservation has been set by a `tlbsrx`. `<E.TWC>` instruction by reading the CR0 field or CR with a `mfocr` or `mfcr` instruction after the `tlbsrx`. `<E.TWC>` and creating a dependency between the data read from CR0 or CR and the address used for the subsequent \textit{Load} instruction.

## Serialization of TLB operations
Regardless of which threads initiated the operations, all operations (reads, writes, invalidates, and searches) involving a single TLB are defined to be serialized such that only one operation occurs at a time. This operation is consistent with the program order of the thread performing the TLB operation. This also applies to a TLB that is shared by multiple threads. Even if there is no matching TLB entry on a `tlbivax`, the TLB is still searched to determine there is no matching entry and this search is still referred to as the TLB invalidation.

If two threads share a TLB and both simultaneously execute a `tlbsrx`. `<E.TWC>` instruction for a virtual address in a virtual page \( V \), and then both threads execute a `TLB Write Conditional` to create a TLB entry for the virtual page \( V \), at most one of these `tlbwe` instructions succeeds.

If, after thread \( P1 \) establishes a TLB-reservation for a virtual address in a virtual page \( V \), another thread \( P2 \) executes a `tlbivax` that invalidates a TLB entry for the virtual page \( V \) and thread \( P1 \) does a `TLB Write Conditional` to create a TLB entry for the virtual page \( V \), then one of the following occurs.

- The TLB invalidation occurs before the TLB write. Thus the TLB-reservation is lost and the `TLB Write Conditional` does not succeed.
- The TLB write occurs before the TLB invalidation. Thus the `TLB Write Conditional` succeeds and the resulting TLB entry created by the `tlbwe` is invalidated by the `tlbivax`.

### Forward progress
Forward progress in loops that use `tlbsrx`. `<E.TWC>` and `tlbwe` with MAS0\textsubscript{WO} = 0b01 is achieved by a cooperative effort among hardware and system software.
The architecture guarantees that when a thread executes a *tibivr* <E.TWC> to set a TLB-reservation for virtual address X and then a *TLB Write Conditional* to write a TLB entry, either

1. the *TLB Write Conditional* succeeds and the TLB entry is written, or
2. the *TLB Write Conditional* fails because the TLB-reservation was reset because some other thread invalidated all TLB entries in the system for the virtual page containing the virtual address X or some other thread wrote a shared TLB entry for the virtual page containing the virtual address X, or
3. the *TLB Write Conditional* fails because the thread's TLB-reservation was lost for some other reason.

In Case 1 forward progress is made in the sense that the thread successfully wrote the TLB entry. In Case 2, the system as a whole makes progress in the sense that either some thread successfully invalidated TLB entries for virtual address X or some thread that shares the TLB wrote a TLB entry for the virtual page containing virtual address X. Case 3 covers TLB-reservation loss required for correct operation of the rest of the system. This includes TLB-reservation loss caused by some other thread invalidating all entries in a shared TLB, as well as TLB-reservation loss caused by system software invalidating all entries for the PID value associated with virtual address X. It may also include implementation-dependent causes of reservation loss.

An implementation may make a forward progress guarantee, defining the conditions under which the system as a whole makes progress. Such a guarantee must specify the possible causes of TLB-reservation loss in Case 3. While the architecture alone cannot provide such a guarantee, the characteristics listed in Cases 1 and 2 are necessary conditions for any forward progress guarantee. An implementation and operating system can build on them to provide such a guarantee.

*Programming Note*

The architecture does not include a “fairness guarantee”. In competing for a TLB-reservation, two threads can indefinitely lock out a third.

### 6.11.4.3 Invalidating TLB Entries

TLB entries may be invalidated by three different methods or if the Embedded.Hypervisor category is supported, by four different methods.

- The TLB entry can be invalidated as the result of a *tibivr* instruction that sets the MAS1γ bit in the entry to 0.
- TLB entries may be invalidated as a result of a *tibiva* instruction or from an invalidation resulting from a *tibiva* on another thread.
- TLB entries may be invalidated as a result of an invalidate all operation specified through appropriate settings in the MMUCSR0.
- If the Embedded.Hypervisor category is supported, TLB entries may be invalidated as a result of a *tibiva* instruction.

See Section 6.11.4.4 for the effects of the above methods on TLB lookaside information.

In systems consisting of a single-threaded processor as well as in systems consisting of multi-threaded processors, invalidations can occur on a wider set of TLB entries than intended. That is, a virtual address presented for invalidation may cause not only the intended TLB targeted for invalidation to be invalidated, but may also invalidate other TLB entries depending on the implementation. This is because parts of the translation mechanism may not be fully specified to the hardware at invalidate time. This is especially true in SMP systems, where the invalidation address must be supplied to all threads in the system, and there may be other limitations imposed by the hardware implementation. This phenomenon is known as generous invalidates. The architecture assures that the intended TLB will be invalidated, but does not guarantee that it will be the only one. A TLB entry invalidated by writing the V bit of the TLB entry to 0 by use of a *tlbwe* instruction is guaranteed to invalidate only the selected TLB entry. Invalidations occurring from *tibiva* or *tibiva* instructions or from *tibiva* instructions on another thread may cause generous invalidates.

The architecture provides a method to protect against generous invalidations. This is important since there are certain virtual memory regions that must be properly mapped to make forward progress. To prevent this, the architecture specifies an IPROT bit for TLB entries. If the IPROT bit is set to 1 in a given TLB entry, that entry is protected from invalidations resulting from *tibiva* <E.HV> and *tibiva* instructions, or from invalidate all operations. TLB entries with the IPROT field set may only be invalidated by explicitly writing the TLB entry and specifying a 0 for the V (MAS1γ) field. This does not preclude the possibility that a TLB entry with the IPROT field set can then invalidate the replaced TLB entry.

To invalidate one or more individual virtual pages from all TLB arrays in all threads without the involvement of software running on other threads, software can execute the following sequence of instructions.

- one or more *tibiva* instructions
- *mbar* or *sync*
- *tibiva* or *tibiva*
Other instructions, excluding \texttt{tlbivax}, may be interleaved with the instruction sequence shown above, but the instructions in the sequence must appear in the order shown. On systems consisting of only a single-threaded processor or on systems where every thread shares every TLB, the \texttt{tlbsync} and the preceding \texttt{mbar} or \texttt{sync} can be omitted.

For the preceding instruction sequence, the \texttt{mbar} or first \texttt{sync} instruction prevents the reordering of \texttt{tlbivax} instructions previously executed by the thread with respect to the subsequent \texttt{tlbsync} instruction. The \texttt{tlbsync} instruction and the subsequent \texttt{sync} instruction together ensure that all storage accesses for which the address was translated using the translations being invalidated will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required and Alternate Coherence Mode attributes, before any data accesses caused by instructions following the \texttt{sync} instruction are performed with respect to that thread or mechanism.

The most obvious issue with generous invalidations is the code memory region that serves as the exception handler for MMU faults. If this region does not have a valid mapping, an MMU exception cannot be handled because the first address of the exception handler will result in another MMU exception.

Not all TLB arrays in a given implementation will implement the IPROT attribute. It is likely that implementations that are suitable for demand page environments will implement it for only a single array, while not implementing it for other TLB arrays.

Operating systems and hypervisors need to use great care when using protected (IPROT) TLB entries, particularly in SMP systems. A system that contains TLB entries on other threads will require a cross thread interrupt or some other synchronization mechanism to assure that each thread performs the required invalidation by writing its own TLB entries.

For MMU Architecture Version 1.0, to ensure a TLB entry that is not protected by IPROT is invalidated if software does not know which TLB array the entry is in, software should issue a \texttt{tlbivax} instruction targeting each TLB in the implementation with the EA to be invalidated.

The preferred method of invalidating entire TLB arrays is invalidation using MMUCSR0, however \texttt{tlbilx} may be more efficient.

Invalidations using MMUCSR0 only affect the TLB array on the thread that performs the invalidation. To perform invalidations on all threads in a coherence domain on a multi-threaded processor or on a system containing multiple single-threaded processors, software should use \texttt{tlbivax}. If a large number of TLB entries need to be invalidated, using MMUCSR0 or, if the Embedded.Hypervisor category is supported, \texttt{tlbilx}, on each thread may be more efficient.

Since a hardware replacement algorithm selects the entry for a \texttt{tlbwe} instruction with \texttt{MAS0HES} = 1, it is typically not possible to invalidate the entry using a second \texttt{tlbwe} instruction with \texttt{MAS0HES} = 1 and \texttt{MAS1V} = 0. If software needs to invalidate a single entry that was written with \texttt{MAS0HES} = 1, software should generally invalidate the entry using \texttt{tlbilx} with T=3 or \texttt{tlbivax}.

6.11.4.4 TLB Lookaside Information

For performance reasons, most implementations also have implementation-specific lookaside information that is used in address translation. This lookaside information is a cache of recently used TLB entries.

If TLBnCFG\_HES=0, lookaside information for the associated TLB array is kept coherent with the TLB and is invisible to software. Any write to the TLB array that displaces or updates an entry will be reflected in the
lookaside information, invalidating the lookaside information corresponding to the previous TLB entry. Any type of invalidation of an entry in TLB will also invalidate the corresponding entry in the lookaside information.

If TLBnCFG_HES=1, lookaside information for the associated TLB array is not required to be kept coherent with the TLB. Only in the following conditions will the lookaside information be kept coherent with the TLB. The MMUCR0 TLB invalidate all will invalidate all lookaside information. The \texttt{tlbilx} and \texttt{tlbivax} instructions invalidate lookaside information corresponding to TLB entry values that are specified to invalidate as well as those TLB entry values that would have been invalidated except for their IPROT=1 value.

The same instructions that synchronize invalidations of TLB entries also synchronize invalidation of TLB lookaside information.

\textbf{Programming Note}

If TLBnCFG_HES=1 for a TLB array and it is important that the lookaside information corresponding to a TLB entry be invalidated, software should use \texttt{tlbilx} or \texttt{tlbivax} to invalidate the virtual address.

6.11.4.5 Invalidating LRAT Entries

There is only one mechanism for invalidating LRAT entries. An LRAT entry can be invalidated as the result of a \texttt{tlbwe} instruction that overwrites the LRAT entry with a new valid entry or that sets LRAT_V = 0. Only one LRAT entry is invalidated by a single \texttt{tlbwe}.

6.11.4.6 Searching TLB Entries

Software may search the MMU by using the \texttt{tlbsx} instruction, and, if Category: TLB Write Conditional category is supported, the \texttt{tlbsrx}. \langle E.TWC \rangle instruction. The \texttt{tlbsrx}, \langle E.TWC \rangle and \texttt{tlbsx} instructions use IND, PID, and AS values from the MAS registers instead of the PID registers and the MSR, and, if the Embedded.Hypervisor category is supported, these instructions use an LPID and GS value from the MAS registers instead LPIDR and MSR. This allows software to search address spaces that differ from the current address space defined by the PID registers. This is useful for TLB fault handling.

6.11.4.7 TLB Replacement Hardware Assist

The architecture provides mechanisms to assist software in creating and updating TLB entries when certain MMU related exceptions occur. This is called TLB Replacement Hardware Assist. Hardware will update the MAS registers on the occurrence of a Data TLB Error Interrupt or Instruction TLB Error interrupt if the Embedded.Hypervisor category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCRDMIUH = 0), or the interrupt is directed to the guest state.

When a Data or Instruction TLB Error interrupt (TLB miss) occurs and if the Embedded.Hypervisor category is not supported, MAS Register updates are enabled for interrupts directed to the hypervisor (EPCRDMIUH = 0), or the interrupt is directed to the guest state, then MAS0, MAS1, and MAS2 are automatically updated using the defaults specified in MAS4 as well as the AS and EPN values corresponding to the access that caused the exception. MAS6 is updated to set MAS6SPID to the value of PID (EPLC\_EPID for External PID Load instructions or EPSC\_EPID for External PID Store instructions), MAS6SIND to the value of MAS4INDD, and MAS6SAS to the value of MSR\_DS or MSR\_IS depending on the type of access (data or instruction) that caused the error. In addition, if MAS4TLBSELD identifies a TLB array that supports NV (Next Victim), MAS0ESEL is loaded with a value that hardware predicts represents the best TLB entry to victimize to create a new TLB entry and MAS0NV is updated with the TLB entry index of what hardware predicts to be the next victim for the set of entries which can be used for translating addresses with the EPN that caused the exception. Thus MAS0ESEL identifies the current TLB entry to be replaced, and MAS0NV points to the next victim. When software writes the TLB entry, the MAS0NV field is written to the TLB array’s set of next victim values. The algorithm used by the hardware to determine which TLB entry should be targeted for replacement is implementation-dependent.

Next Victim support is provided for TLB arrays that are set associative and that have TLBnCFG_HES=0. Next Victim support is not provided for TLB arrays that are fully associative.

The automatic update of the MAS registers sets up all the necessary fields for creating a new TLB entry with the exception of RPN, the U0-U3 attribute bits, and the permission bits. With the exception of the upper 32 bits of RPN and the page attributes (should software desire to specify changes from the default attributes), all the remaining fields are located in MAS3, requiring only the single MAS register manipulation by software before writing the TLB entry.

For Instruction Storage interrupt (ISI) and Data Storage interrupt (DSI) related exceptions, the MAS registers are not updated. Software must explicitly search the TLB to find the appropriate entry.

The update of MAS registers through TLB Replacement Hardware Assist is summarized in Table 11 on page 1116.
6.11.4.8 32-bit and 64-bit Specific MMU Behavior

MMU behavior is largely unaffected by whether the thread is in 32-bit computation mode (MSR\textsubscript{CM}=0) or 64-bit computation mode (MSR\textsubscript{CM}=1). The only differences occur in the EPN field of the TLB entry and the EPN field of MAS2. The differences are summarized here.

- Executing a \texttt{tlbwe} instruction in 32-bit mode will set bits 0:31 of the TLB EPN field to zero unless \texttt{MAS0ATSEL} is set, in which case those bits are not written to zero.
- For an update to MAS registers via TLB Replacement Hardware Assist (see Section 6.11.4.7), an update to bits 0:53 of the EPN field occurs regardless of the computation mode of the thread at the time of the exception or the interrupt computation mode in which the interrupt is taken. If the instruction causing the exception was executing in 32-bit mode, bits 0:31 of the EPN field in MAS2 will be set to 0.
- Executing a \texttt{tlbre} instruction in 32-bit mode will set bits 0:31 of the MAS2 EPN field to an undefined value.
- In 32-bit implementations, MAS2U can be used to read or write EPN\textsubscript{0:31} of MAS2.

\textbf{Programming Note}

This allows a 32-bit OS to operate seamlessly in 32-bit mode on a 64-bit implementation and a 64-bit OS to easily support 32-bit applications.
6.11.4.9 TLB Management Instructions

The `tlbivax` instruction is used to invalidate TLB entries. Additional instructions are used to read and write, and search TLB entries, and to provide an ordering function for the effects of `tlbivax`. If the Embedded.Hypervisor category is supported, the `tlbilx` instruction is used to invalidate TLB entries in the thread executing the `tlbilx`.

**TLB Invalidate Virtual Address Indexed X-form**

```
tlbivax RA, RB
```

| 31  | 16 | 11 | 6 | 21 | 786 | /
<table>
<thead>
<tr>

<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>b</td>
<td>RA</td>
<td>RB</td>
<td></td>
<td></td>
<td>31</td>
</tr>
</tbody>
</table>

For each thread:
- If MAV = 1.0 then for TLB array = EA59:60
- If MAV = 2.0 then for each TLB entry
  - If MMUCFGTWC = 1 or TLBnCFGHES = 1 then
    - c = MAS6ISIZE
  - Else
    - c = entrySIZE
  - If (MV = 1.0) then
    - m = ¬((1 << (2×c)) - 1)
  - Else
    - m = ¬((1 << c) - 1)
  - If ((EA0:53 & m) = (entryEPN & m)) &
    - entrySIZE = MAS6ISIZE &
    - entryTID = MAS6SPID & entryTGS = MAS5SGS &
    - (E.PT not supported | entryTID = MAS5SIND) &
    - (E.HV not supported |
      - entryTLPID = MAS5SLPID &
      - entryTGS = MAS5SGS)) &
    - (MAV = 1.0) & (EA61 = 1)
    - then
    - if entryIPROT = 0 then entryV ← 0

Let the effective address (EA) be the sum (RA|0)+(RB). The EA is interpreted as shown below.

- **EA0:53**
  - **EA61:63** Reserved
- **EA59:60** TLB array selector [MAV = 1.0]
  - 00 TLB0
  - 01 TLB1
  - 10 TLB2
  - 11 TLB3
- **EA61** TLB invalidate all [MAV = 1.0]
- **EA62:63** Reserved

If EA61=0, all TLB entries on all threads that have all of the following properties are made invalid. The MAS registers listed are those in the thread executing the `tlbivax`.
- The MMU architecture version is 2.0 or the entry is in the TLB array targeted by EA59:60.
- The logical AND of EA0:53 and m is equal to the logical AND of the EPN value of the TLB entry and m, where m is based on the following.
  - If MMUCFGTWC = 1 or TLBnCFGHES = 1, c is equal MAS6ISIZE. Otherwise, c is equal to entrySIZE.
  - If MMU Architecture Version 1.0 is supported, m is equal to the logical NOT of ((1 << (2×c)) - 1). Otherwise, m is equal to the logical NOT of ((1 << c) - 1).
- The TID value of the TLB entry is equal to MAS6SPID and the TS value of the TLB entry is equal to MAS6SAS.
- The implementation does not support the Embedded.Page Table category or the IND value of the TLB entry is equal to MAS5SIND.
- Either of the following is true:
  - The implementation does not support the Embedded.Hypervisor category.
  - The TLPIP value of the TLB entry is equal to MAS5SLPID and the TGS value of the TLB entry is equal to MAS5SGS.
  - entryIPROT = 0.

In MMU Architecture Version 1.0 if EA61=1, all entries in all threads not protected by the IPROT attribute in the TLB array targeted by EA59:60 are made invalid.

If the instruction specifies a TLB array that does not exist, the instruction is treated as if the instruction form is invalid. If the implementation requires the page size to be specified by MAS6ISIZE (MMUCFGTWC = 1 or, for the specified TLB array, TLBnCFGHES = 1) and the page size specified by MAS6ISIZE is not supported by the implementation, the instruction is treated as if the instruction form is invalid.

If the operation isn’t a TLB invalidate all and there are multiple entries in a single thread’s TLB array(s) that match the complete VPN, then zero or more matching entries with IPROT=0 are invalidated or a Machine Check interrupt occurs. If the Embedded.Hypervisor category is supported, this Machine Check interrupt must be precise.

The operation performed by this instruction is ordered by the `mbar` (or `sync`) instruction with respect to a subsequent `tlbsync` instruction executed by the thread executing the `tlbivax` instruction. The operations caused by `tlbivax` and `tlbsync` are ordered by `mbar` as a set of operations which is independent of the other sets that `mbar` orders.

The effects of the invalidation on this thread are not guaranteed to be visible to the programming model.
until the completion of a context synchronizing operation.

Invalidations may occur for other TLB entries in the designated array, but in no case will any TLB entries with the IPROT attribute set be made invalid.

If RA does not equal 0, it is implementation-dependent whether an Illegal Instruction exception occurs.

If the Embedded.Hypervisor category is supported, this instruction is hypervisor privileged. Otherwise, this instruction is privileged.

**Special Registers Altered:**

None

---

**Programming Note**

Care must be taken not to invalidate any TLB entry that contains the mapping for any interrupt vector.

For backward compatibility, implementations may ignore a TLB entry's TS and TID fields when determining whether an entry should be invalidated. Since this and other such generous invalidation can be performed, consideration should be given to protecting a TLB entry that maps an interrupt vector by setting TLBIPROT = 1.

---

**Programming Note**

The `tlbilx` instruction is the preferred way of performing TLB invalidations for operating systems running as a guest to the hypervisor since the invalidations are partitioned and do not require hypervisor privilege.

---

**Programming Note**

The TLB invalidate all function (EA61=1) only exists in MMU Architecture Version 1.0 implementations. It should only be used when running existing software is deemed important.

entryV ← 0

Let the effective address (EA) be the sum (RA|0) + (RB).

The *tlbilx* instruction invalidates TLB entries in the thread that executes the *tlbilx* instruction. TLB entries which are protected by the IPROT attribute (entryIPROT = 1) are not invalidated.

If T = 0, all TLB entries that have all of the following properties are made invalid on the thread executing the *tlbilx* instruction.
- The TLPID of the entry matches MAS5SLPID.
- The IPROT of the entry is 0.

If T = 1, all TLB entries that have all of the following properties are made invalid on the thread executing the *tlbilx* instruction.
- The TLPID of the entry matches MAS5SLPID.
- The TID of the entry matches MAS6SPID.
- The IPROT of the entry is 0.

If T = 3, all TLB entries in the thread executing the *tlbilx* instruction that have all of the following properties are made invalid.
- The TLPID of the value of the TLB entry is equal to MAS5SLPID and the TGS value of the TLB entry is equal to MAS5SGS.
- The logical AND of EA0:53 and m is equal to the logical AND of the EPN value of the TLB entry and m, where m is based on the following.

- If MMUCFGTWC = 1 or TLBnCFGHES = 1, c is equal MAS6ISIZE. Otherwise, c is equal to entrySIZE.
- If MMU Architecture Version 1.0 is supported, m is equal to the logical NOT of ((1 <<< (2 × c)) - 1). Otherwise, m is equal to the logical NOT of ((1 <<< c) - 1).
- The TID value of the TLB entry is equal to MAS6SPID and the TS value of the TLB entry is equal to MAS6SAS.
- The implementation does not support the Embedded.Page Table category or the IND value of the TLB entry is equal to MAS6SIND.
- The IPROT of entry is 0.

The effects of the invalidation are not guaranteed to be visible to the programming model until the completion of a context synchronizing operation.

Invalidations may occur for other TLB entries on the thread executing the *tlbilx* instruction, but in no case will any TLB entries with the IPROT attribute set be made invalid.

If T = 2, the instruction form is invalid.

If T = 3 and the implementation requires the page size to be specified by MAS6ISIZE (MMUCFGTWC = 1 or, for any TLB array, TLBnCFGHES = 1) and the page size specified by MAS6ISIZE is not supported by the implementation, the instruction is treated as if the instruction form is invalid.

If T=3 and there are multiple entries in the TLB array(s) that match the complete VPN, then zero or more matching entries with IPROT=0 are invalidated or a Machine Check interrupt occurs. If the Embedded.Hypervisor category is supported, this Machine Check interrupt must be precise.

If RA does not equal 0, it is implementation-dependent whether an Illegal Instruction exception occurs.

If the Embedded.Hypervisor category is supported and guest execution of TLB Management instructions is disabled (EPCR[DGTM]=1), this instruction is hypervisor privileged. Otherwise, this instruction is privileged.

**Special Registers Altered:**

None

**Extended Mnemonics:**

Examples of extended mnemonics for *TLB Invalidate Local*:

<table>
<thead>
<tr>
<th>Extended:</th>
<th>Equivalent to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>tlbilxpid</td>
<td>tlbilx 0,0,0</td>
</tr>
<tr>
<td>tlbixpid</td>
<td>tlbilx 1,0,0</td>
</tr>
<tr>
<td>tlbilxva</td>
<td>tlbilx 3,RA,RB</td>
</tr>
<tr>
<td>tlbilxva</td>
<td>tlbilx 3,0,RB</td>
</tr>
</tbody>
</table>
Programming Note

tlbix is the preferred way of performing TLB invalidations, especially for operating systems running as a guest to the hypervisor since the invalidations are partitioned and do not require hypervisor privilege.

Programming Note

When dispatching a guest operating system, hypervisor software should always set MAS5SLPID to the guest's corresponding LPID value.

Programming Note

Executing a tlbix instruction with T=0 or T=1 may take many cycles to perform. Software should only issue these operations when an LPID or a PID value is reused or taken out of use.

Let the effective address (EA) be the sum (RA|0)+ (RB).
If the search is successful, MAS register fields are loaded from the matching TLB entry according to the following:

- **MAS0ATSEL** is set to 0.
- **MAS0TLBSEL** is set to the number of the TLB array with the matching entry.
- **MAS0ESEL** is set to the index of the matching entry.
- If **MAS0HES** is supported, **MAS0HES** is set to 0.
- If Next Victim is supported for any TLB array, the following applies:
  - If the TLB array with the matching entry supports Next Victim, **MAS0NV** is set to 0.
  - Otherwise, **MAS0NV** is set to an implementation-dependent undefined value.
- **MAS1V** is set to 1.
- **MAS1TIDTS** are loaded from the TID, TS, and SIZE fields of the TLB entry.
- If the TLB array supports IPROT, **MAS1IPROT** is loaded from the IPROT bit of the TLB entry. Otherwise, **MAS1IPROT** is set to 0.
- **MAS2EPN** are loaded from the EPN, W, I, M, G, and E fields of the TLB entry.
- If the VLE category is supported, **MAS2VLE** is loaded from the VLE bit of the TLB entry.
- If Alternate Coherency Mode is supported, **MAS2ACM** is loaded from the ACM bit of the TLB entry.
- **MAS3RPNL** is loaded from the lower 22-bits of the RPN field of the TLB entry, and, if implemented, **MAS7RPNU** is loaded from the upper 32-bits of the RPN field of the TLB entry.
- The supported User-Defined storage control bits in **MAS3UX** are loaded from the respective supported U0:U3 bits of the TLB entry.
- If the Embedded.Page Table category is not supported, **MAS3UX** are loaded from the UX, SX, UW, SW, UR, and SR bits of the TLB entry. Otherwise, the following applies.
  - If the TLB array does not support indirect entries, **MAS1IND** is set to 0 and **MAS3UX** are loaded from the UX, SX, UW, SW, UR, and SR bits of the TLB entry. Otherwise, the following applies.
    - **MAS1IND** is loaded from the IND bit of the TLB entry.
    - If the IND bit of the TLB entry is 1, **MAS3SPSIZE** is loaded from the SPSIZE field of the TLB entry, and **MAS3UND** is set to an implementation-dependent undefined value.
    - If the IND bit of the TLB entry is 0, **MAS3UX** are loaded from the UX, SX, UW, SW, UR, and SR bits of the TLB entry.
- If the Embedded.Hypervisor category is implemented, **MAS8TGS** are loaded from the TGS, VF, and TLPID fields of the TLB entry.

If no valid matching translation exists, **MAS1V** is set to 0 and the MAS register fields are loaded according to the following in order to facilitate a TLB replacement:

- **MAS0ATSEL** is set to 0.
- **MAS0TLBSEL** is loaded from **MAS4TLBSELD**.
- If Next Victim is not supported for any TLB array, **MAS0ESEL** is set to an implementation-dependent undefined value. Otherwise, the following applies.
  - If the TLB array specified by **MAS4TLBSELD** supports Next Victim, **MAS0NV** is set to the hardware hint for the index of the entry to be replaced and **MAS0NV** is set to the hardware hint for the index of the next entry to be replaced. Otherwise, **MAS0ESEL** and **MAS0NV** are set to implementation-dependent undefined values.
- If **MAS0HES** is supported, **MAS0HES** is set to the value of **TLBnCFGHES** for the TLB array specified by **MAS4TLBSELD**.
- **MAS1IPROT** is set to 0.
- **MAS1TIDTS** are loaded from **MAS6SPID**.
- **MAS1TSIZE** is loaded from **MAS4TSIZED**.
- If the Embedded.Page Table category is supported, **MAS1IND** is set to **MAS4IND**.
- **MAS2EPN** is set to an implementation-dependent undefined value.
- **MAS2W** are loaded from **MAS4WD**.
- **MAS2ACM** is loaded from **MAS4ACMD**.
- **MAS2VLE** is loaded from **MAS4VLED**.
- **MAS2ACM** and, if implemented, **MAS7RPNU** are set to 0.
- The supported User-Defined storage control bits in **MAS3UX** are set to 0.
- **MAS3UX** are loaded from the UX, SX, UW, SW, UR, and SR bits of the TLB entry.
- **MAS0WQ** is set to 0b01.

If a **tlbsx** is successful, it is considered to “hit”. Otherwise, it is considered to “miss”.

If there are multiple matching TLB entries, either one of the matching entries is used or a Machine Check exception occurs. If the Embedded.Hypervisor category is supported, this Machine Check interrupt must be precise.

If RA does not equal zero, it is implementation-dependent whether an illegal instruction exception occurs.

If the Embedded.Hypervisor category is supported, this instruction is hypervisor privileged. Otherwise, this instruction is privileged.

**Special Registers Altered:**
- **MAS0**
- **MAS1**
- **MAS2**
- **MAS3**
- **MAS7**
- **MAS8** (if category E.HV supported)

Let the effective address (EA) be the sum (RA|0)+
(RB).

If any TLB array contains a valid entry matching the MAS1IND <E.PT> and virtual address formed by
MAS5SGS <E.HV>, MAS5SLPID <E.HV>, MAS1TS TID, and EA, the search is considered successful. A TLB
entry matches if all the following conditions are met.

- The valid bit of the TLB entry is 1.
- Either the Embedded.Page Table category is not supported or the IND value of the TLB entry is equal to
  MAS1IND.
- The logical AND of EA0:53 and m is equal to the logical AND of the EPN value of the TLB entry and m,
  where m is determined as follows:
  - If MMU Architecture Version 1.0 is supported, m is equal to the logical NOT of ((1 << entrySIZE) - 1).
  - Otherwise, m is equal to the logical NOT of ((1 << entrySIZE) - 1).
- The TID value of the TLB entry is equal to MAS1TID or is zero.
- The TS value of the TLB entry is equal to MAS1TS.
- Either of the following is true:
  - The implementation does not support the Embedded.Hypervisor category.
  - The TGS value of the TLB entry is equal to MAS5SGS and either the TLPID value of the TLB entry is equal to
    MAS5SLPID or is zero.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the search was successful.

CR0LT GT EQ SO = 0b00 || n || 0

This instruction creates a TLB-reservation for use by a TLB Write instruction. The virtual address described
above is associated with the TLB-reservation, and replaces any address previously associated with
the TLB-reservation. (The TLB-reservation is created regardless of whether the search succeeds.)

If there are multiple matching TLB entries, either one of
the matching entries is used or a Machine Check
exception occurs. If the Embedded.Hypervisor cate-
gory is supported, this Machine Check interrupt must
be precise.

If RA does not equal zero, it is implementation-depen-
dent whether an Illegal Instruction exception occurs.

If the Embedded.Hypervisor category is supported and
guest execution of TLB Management instructions is dis-
abled (EPCR DGTMI=1), this instruction is hypervisor
privileged. Otherwise, this instruction is privileged.

if Next Victim is supported for any TLB array, the following applies.
  If the Embedded.Hypervisor.LRAT category is not supported or MAS0ATSEL = 0, then the following applies.
  - If Next Victim is supported for any TLB array, the following applies.
    - If the TLB array specified by MAS0TLBSEL supports Next Victim, MAS0NV is set to the hardware hint for the index of the entry to be replaced. Otherwise, MAS0NV is set to a non-hint value.
  - A TLB entry is selected in one of the following ways.
    - If TLBnCFGHES = 0 for the TLB array selected by MAS0TLBSEL, the TLB entry is specified by MAS0TLBSEL, MAS0ESEL and MAS2EPN.
    - If TLBnCFGHES = 1 for the TLB array selected by MAS0TLBSEL, the TLB entry is specified by MAS0TLBSEL, MAS0ESEL and a hardware generated hash based on MAS1TID, MAS1TSIZE, and MAS2ESEL.
  - If the selected TLB entry exists, MAS register fields are loaded according to the following.
    - MAS1V TID TSIZE are loaded from the V, TID, TS, and SIZE fields of the TLB entry.
    - If the TLB array supports IPROT, MAS1IPROT is loaded from the IPROT bit of the TLB entry. Otherwise, MAS1IPROT is set to 0.
    - If ACM supported then MAS2ACM is set to 0.
    - If VLE category is supported, MAS2VLE is loaded from the VLE bit of the TLB entry.
    - If Alternate Coherency Mode is supported, MAS2ACM is loaded from the ACM bit of the TLB entry.
MAS3RPNL is loaded from the lower 22-bits of the RPN field of the TLB entry, and, if implemented, MAS7RPNU is loaded from the upper 32-bits of the RPN field of the TLB entry.

The supported User-Defined storage control bits in MAS3UX:U3 are loaded from the respective supported UX:U3 bits of the TLB entry.

If the Embedded.Page Table category is not supported, MAS3UX:UX, SW:SW, UR:UR, and SR:SR bits of the TLB entry. Otherwise, the following applies.

- If the TLB array does not support indirect entries, MAS1IND is set to 0 and MAS3UX:UX, UW:UW, SW:SW, UR:UR, and SR:SR bits of the TLB entry. Otherwise, the following applies.
  - If the IND bit of the TLB entry is 1, MAS1V is set to 0 and the following MAS register fields are set to implementation-dependent undefined values.
  - If the IND bit of the TLB entry is 0, MAS3UX:UX, SW:SW, UR:UR, and SR:SR bits of the TLB entry.

If the Embedded.Hypervisor category is implemented, MAS8TGS:VFTLPID are loaded from the TGS, VF, and TLPID fields of the TLB entry.

If the Embedded.Hypervisor category is supported, the LRAT array is specified (MAS0ATSEL = 1), then the following applies.

- If the LRAT entry specified by MAS0ESEL and MAS2EPN exists, MAS register fields are loaded from the LRAT entry according to the following.
  - MAS1V is loaded from the V and LSIZE fields of the LRAT entry.
  - MAS1IPROT TID:TSIZE, MAS2EPN W I M G E, and MAS3UX:UX, SW:SW, UR:UR, and SR:SR are set to 0s.
  - If the Embedded.Page Table category is supported, MAS1IND is set to 0.
  - If the VLE category is supported, MAS2VLE is set to 0.
  - If Alternate Coherency Mode is supported, MAS2ACM is set to 0.
  - If Alternate Coherency Mode is supported, MAS3RPNL is loaded from the lower 22-bits of the LRPN field of the LRAT entry, and, if implemented, MAS7RPNU is loaded from the upper 32-bits of the LRPN field of the LRAT entry.
  - The supported User-Defined storage control bits in MAS3UX:UX are set to 0s.
  - MAS8TGS:VF are set to 0s.

If the Embedded.Page Table category is supported (TLBnCFGoured = 1), MAS8TLPID is loaded from the TLPID field of the LRAT entry.

If TLBnCFGoured = 1 and the page size specified by MAS1TSIZE is not supported by the specified array, the *tlbre* may be performed as if TSIZE were some implementation-dependent value of or, as described below, as if the entry can not be found, or an Illegal Instruction exception occurs.

It is implementation-dependent whether a TLB or LRAT entry can not be found or whether larger values of the fields that select an entry are simply mapped to existing entries. If the specified TLB or LRAT entry does not exist, MAS1V is set to 0 and the following MAS register fields are set to implementation-dependent undefined values.

- MAS1IPROT TID:TSIZE, MAS2EPN W I M G E, and MAS3UX:UX, SW:SW, UR:UR, and SR:SR are set to 0s.
- If the Embedded.Page Table category is supported, MAS1IND is set to 0.
- If the VLE category is supported, MAS2VLE is set to 0.
- If Alternate Coherency Mode is supported, MAS2ACM is set to 0.
- The supported User-Defined storage control bits in MAS3UX:UX are set to 0s.
- If the Embedded.Hypervisor category is supported, this instruction is hypervisor privileged. Otherwise, this instruction is privileged.

**Special Registers Altered:**

- MAS0
- MAS1
- MAS2
- MAS3
- MAS8 (if category E.HV is supported)

**Programming Note**

Hypervisor software should generally prevent guest operating system visibility of the RPN. After executing a *tlbsx* or *tlbre* on behalf of a guest, the hypervisor should replace the RPN fields in the MAS3 and MAS7 registers with the corresponding values from the appropriate LPN.

<th>16</th>
<th>21</th>
<th>566</th>
<th>31</th>
</tr>
</thead>
</table>

The `tlbsync` instruction provides an ordering function for the effects of all `tlbivax` instructions executed by the thread executing the `tlbsync` instruction, with respect to the memory barrier created by a subsequent `sync` instruction executed by the same thread. Executing a `tlbsync` instruction ensures that all of the following will occur.

- All TLB invalidations caused by `tlbivax` instructions preceding the `tlbsync` instruction will have completed on any other thread before any data accesses caused by instructions following the `sync` instruction are performed with respect to that thread.
- All storage accesses by other threads for which the address was translated using the translations being invalidated will have been performed with respect to the thread executing the `sync` instruction, to the extent required by the associated Memory Coherence Required attributes, before the `sync` instruction's memory barrier is created.

The operation performed by this instruction is ordered by the `mbar` or `sync` instruction with respect to preceding `tlbivax` instructions executed by the thread executing the `tlbsync` instruction. The operations caused by `tlbivax` and `tlbsync` are ordered by `mbar` as a set of operations, which is independent of the other sets that `mbar` orders.

The `tlbsync` instruction may complete before operations caused by `tlbivax` instructions preceding the `tlbsync` instruction have been performed.

If the Embedded.Hypervisor category is supported, this instruction is hypervisor privileged. Otherwise, this instruction is privileged.

**Special Registers Altered:**

- None

---

**Programming Note**

Care must be taken on some implementations when using the `tlbsync` instruction as there may be a system-imposed restriction of only one `tlbsync` allowed on the bus at a given time in the system.

entryTGS VF TLPID `← MAS8TGS VF TLPID`
if category E.TWC supported
TLB-reservation `← 0`
else
  entry `← SelectLRAT(MAS0ESEL, MAS2EPN)`
  if LRAT entry is found & (`MAS0WQ = 0b00`) & (MAS0HES = 0b0) then
    hint `← MAS0NV`
  entryRLR `← pull(MAS1VPNL, hardware_replacement_algorithm)`
  else
    if category E.TWC supported
      TLB-reservation `← 0`
If the Embedded.TLB Write Conditional category is not supported, MAS0WQ is treated as if it were 0b00 in the following description.

If the Embedded.Hypervisor.LRAT category is not supported or MSRGS=1, MAS0ATSEL is treated as if it were zero in the following description.

If a TLB array is specified (MAS0ATSEL = 0 or MSRGS = 1) and TLBnCFGHES=0 for the TLB array selected by MAS0TLBSEL, MAS0HES is treated as 0 in the following description.

If the Embedded.Page Table category is supported, a TLB array is specified (MAS0ATSEL = 0 or MSRGS = 1), and the specified TLB array does not support indirect entries, MAS1IND is treated as 0.

If a TLB array is specified (MAS0ATSEL = 0 or MSRGS = 1) and MAS0WQ is 0b00 or 0b01, the following applies.

- If the Embedded.Hypervisor is not supported, the tlbwe instruction is executed in hypervisor state, or MAS1v=0, an RPN is formed by concatenating MAS7RPNU with MAS3RPNL (RPN = MAS7RPNU || MAS3RPNL).
- If the Embedded.Hypervisor category is supported, the tlbwe instruction is executed in guest state, and MAS1v=1, an LPN is formed by concatenating MAS7RPNU with MAS3RPNL (LPN = MAS7RPNU || MAS3RPNL). However, if MAS7 is not implemented, LPN = 320 || MAS3RPNL. This LPN is translated by the LRAT to obtain the RPN. If there is no LRAT entry that translates this LPN for the LPIID specified by MAS8TLPID an LRAT Miss exception occurs. However, if MAS0WQ is 0b01 and no TLB-reservation exists, it is implementation-dependent whether the LRAT Miss exception occurs.
- If TLBnCFGHES for the TLB array selected by MAS0TLBSEL is 0, the TLB entry is specified by MAS0TLBSEL, MAS0SESEL, and MAS2EPN. If TLBnCFGHES is 1 and MAS0HES is 1, the TLB entry is selected by MAS0TLBSEL, a hardware replacement algorithm, and a hardware generated hash based on MAS1TID TSIZE, and MAS2EPN. If TLBnCFGHES is 1 and MAS0HES is 0, the TLB entry is selected by MAS0TLBSEL, MAS0SESEL and a hardware generated hash based on MAS0TLBSEL, MAS1TID TSIZE, and MAS2EPN.
- The selected TLB entry is written (see the following major bulleted item) if all the following conditions are met.
  - There is no LRAT Miss exception.
  - MAS0WQ is 0b00 or both the following are true.
    - MAS0WQ is 0b01
    - A TLB-reservation exists.
  - MAS1IPROT is 0, the Embedded.Hypervisor category is not supported, or MSRGS=0.
  - The selected TLB entry has IPROT = 0, the Embedded.Hypervisor category is not supported, or MSRGS=0.
- If the Embedded.Hypervisor category is supported, use the first of the following sub-bullets that applies.
  - If EPCR<DTMI>=1 and MSRGS=1, no TLB entry is written and a Hypervisor Privilege exception occurs.
  - If the selected entry exists, the selected entry has IPROT=1, MAS0WQ=0b00, and MSRGS=1, no TLB entry is written, and a Hypervisor Privilege exception occurs.
  - If MAS0WQ=0b00, MAS1v=1, MAS1IPROT=1, and MSRGS=1, no TLB entry is written, and it is implementation-dependent whether a Hypervisor Privilege exception occurs.
  - If MAS0WQ=0b00, MAS1v=0, MAS1IPROT=1, and MSRGS=1, no TLB entry is written, and it is implementation-dependent whether a Hypervisor Privilege exception occurs.

If a TLB entry is to be written per the preceding description, then regardless of whether the selected TLB entry exists, MAS0VU provides a suggestion to hardware of what the hardware hint for replacement should be when the next Data or Instruction TLB Error Interrupt for a virtual address that uses the set of TLB entries containing the entry written by the tlbwe instruction.

If the selected TLB entry exists and the TLB entry is to be written per the preceding description, the fields of the TLB entry are loaded from the MAS registers according to the following.

- The V, TID, TS, and SIZE fields of the TLB entry are loaded from MAS1V TID TS SIZE.
- If the TLB array supports IPROT, the IPROT bit of the TLB entry is loaded from MAS1IPROT.
- The EPN, W, I, M, G, and E fields of the TLB entry are loaded from MAS2EPN W I M G E.
- If the VLE category is supported, the VLE bit of the TLB entry is loaded from MAS2VLE.
- If Alternate Coherency Mode is supported, the ACM bit of the TLB entry is loaded from MAS2ACM.
- The RPN field of the TLB entry is loaded from the RPN described above.
- The supported User-Defined storage control bits (U0:U3) of the TLB entry are loaded from the respective bits in MAS3U0:U3.
- If the Embedded.Page Table category is supported and the TLB array supports indirect entries, the following applies.
The IND of the TLB entry is loaded from MAS1\textsubscript{IND}.
- If MAS1\textsubscript{IND} is 1, the SPSIZE field of the TLB entry is loaded from MAS3\textsubscript{SPSIZE}.
- If MAS1\textsubscript{IND} is 0, the UX, SX, UW, SW, UR, and SR bits of the TLB entry are loaded from MAS3\textsubscript{UX} SX UW SW UR SR.
- If the Embedded.Page Table category is not supported or the TLB array does not support indirect entries, the UX, SX, UW, SW, UR, and SR bits of the TLB entry are loaded from MAS3\textsubscript{UX} SX UW SW UR SR.
- If the Embedded.Hypervisor category is implemented, the TGS, VF, and TLPID fields of the TLB entry are loaded from MAS8\textsubscript{TGS} VF TLPID.

If the LRAT array is specified (MAS0\textsubscript{ATSEL} = 0 or MSR\textsubscript{GS} = 1) for a \texttt{tlbwe}, MAS0\textsubscript{WQ} must be 0b00 and MAS0\textsubscript{HES} must be 0. If the LRAT array is specified (MAS0\textsubscript{ATSEL} = 0 or MSR\textsubscript{GS} = 1), MAS0\textsubscript{WQ} is 0b00, MAS0\textsubscript{HES} is 0, and the \texttt{tlbwe} instruction is executed in hypervisor state, the following applies.
- An RPN is formed by concatenating MAS7\textsubscript{RPNU} with MAS3\textsubscript{RPNL} (RPN = MAS7\textsubscript{RPNU} || MAS3\textsubscript{RPNL}).
- The contents of the MAS1\textsubscript{V} TSIZE, MAS2\textsubscript{EPN}, and the RPN described above are written to the selected LRAT entry\textsubscript{V} LSIZE LPN RPN.
- If the LPID field in the LRAT is supported (LRATCFG\textsubscript{LPID} = 1), MAS8\textsubscript{TLPID} is written to the LPID field of the selected entry.

If no exception occurs, and either MAS0\textsubscript{WQ} is 0b10 or a TLB array was selected by the \texttt{tlbwe} (MAS0\textsubscript{ATSEL}=0 or MSR\textsubscript{GS}=1), the TLB-reservation is cleared.
- If MAS0\textsubscript{WQ} is 0b10, no TLB entry is written.
- If MAS0\textsubscript{WQ} is 0b11, the instruction is treated as if the instruction form is invalid.

If the page size specified by MAS1\textsubscript{TSIZE} is not supported by the specified array, the \texttt{tlbwe} may be performed as if TSIZE were some implementation-dependent value, or an Illegal Instruction exception occurs.

If a TLB entry is to be written per the preceding description, MAS1\textsubscript{IND}=1, and values of I,M,G, and E to be written to the TLB entry are inconsistent with storage that is not Caching Inhibited, Memory Coherence Required, not Guarded, and Big-Endian, the \texttt{tlbwe} may be performed as described or an Illegal Instruction exception occurs. Also, if a TLB entry is to be written per the preceding description, MAS1\textsubscript{IND}=1, and values of ACM and U0:U3 to be written to the TLB entry are inconsistent with the requirements that an implementation has for storage control attributes for a Page Table, the \texttt{tlbwe} may be performed as described or an Illegal Instruction exception occurs.

If an invalid value is specified for MAS0\textsubscript{TLBSEL} MAS0\textsubscript{ESEL} or MAS2\textsubscript{EPN}, either no TLB entry is written by the \texttt{tlbwe}, or the \texttt{tlbwe} is performed as if some implementation-dependent, valid value were substituted for the invalid value, or an Illegal Instruction exception occurs.

A context synchronizing instruction is required after a \texttt{tlbwe} instruction to ensure any subsequent instructions that will use the updated TLB or LRAT values execute in the new context.

If TLBnCFG\textsubscript{HES}=1 for the selected TLB array, a TLB write does not necessarily invalidate implementation-specific TLB lookaside information. See Section 6.11.4.4.

This instruction is hypervisor privileged if the Embedded.Hypervisor category is supported and any of the following is true.
- The Embedded.Hypervisor.LRAT category is not supported.
- MSR\textsubscript{GS} = 1 and, for the TLB array selected by MAS0\textsubscript{TLBSEL}, TLBnCFG\textsubscript{GTWE} = 0.
- Guest execution of \textit{TLB Management} instructions is disabled (EPCR\textsubscript{DGTMI}=1).

Otherwise, this instruction is privileged.

**Special Registers Altered:**
None

### Programming Note
Care must be taken not to invalidate any TLB entry that contains the mapping for any interrupt vector.
Chapter 7. Interrupts and Exceptions

7.1 Overview

An interrupt is the action in which the thread saves its old context (MSR and next instruction address) and begins execution at a pre-determined interrupt-handler address, with a modified MSR. Exceptions are the events that will, if enabled, cause the thread to take an interrupt.

Exceptions are generated by signals from internal and external peripherals, instructions, the internal timer. Interrupts are divided into 4 classes, as described in Section 7.4.3, such that only one interrupt of each class is reported, and when it is processed no program state is lost. Since Save/Restore register pairs GSRR0/GSRR1 <E.HV> SRR0/SRR1, CSRR0/CSRR1, DSRR0/DSRR1 [Category: E.ED], and MCSSR0/MCSSR1 are serially reusable resources used by guest <E.HV>, base, critical, debug [Category: E.ED], Machine Check interrupts, respectively, program state may be lost when an unordered interrupt is taken. (See Section 7.8, "Interrupt Ordering and Masking".

7.2 Interrupt Registers

7.2.1 Save/Restore Register 0

Save/Restore Register 0 (SRR0) is a 64-bit register. SRR0 bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on non-critical interrupts, and to restore machine state when an rfi is executed. On a non-critical interrupt, SRR0 is set to the current or next instruction address. When rfi is executed, instruction execution continues at the address in SRR0.

```
<table>
<thead>
<tr>
<th>SRR0</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>
```

Figure 53. Save/Restore Register 0

In general, SRR0 contains the address of the instruction that caused the non-critical interrupt, or the address of the instruction to return to after a non-critical interrupt is serviced.

The contents of SRR0 when an interrupt is taken are mode dependent, reflecting the computation mode when the interrupt is taken and the computation mode entered for execution of the interrupt (specified by EPCRiCm) <E.HV>. When computation mode when the interrupt is taken is 32-bit mode and the computation mode entered for execution of the interrupt is 64-bit mode, the high-order 32 bits of SRR0 are set to 0s. When computation mode when the interrupt is taken is 64-bit mode and the computation mode entered for execution of the interrupt is 32-bit mode, the contents SRR0 are undefined.

The contents of SRR0 upon interrupt can be described as follows (assuming Addr is the address to be put into SRR0):

- if (MSRCM = 0) & (EPCRICM = 0) then SRR0 ← 32undefined || Addr32:63
- if (MSRCM = 0) & (EPCRICM = 1) then SRR0 ← 320 || Addr32:63
- if (MSRCM = 1) & (EPCRICM = 1) then SRR0 ← Addr0:63
- if (MSRCM = 1) & (EPCRICM = 0) then SRR0 ← undefined

The contents of SRR0 can be read into register RT using mfspr RT,SRR0. The contents of register RS can be written into the SRR0 using mtspr SRR0,RS.

This register is hypervisor privileged.

7.2.2 Save/Restore Register 1

Save/Restore Register 1 (SRR1) is a 32-bit register. SRR1 bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on non-critical interrupts, and to restore machine state when an rfi is executed. On a non-critical interrupt, SRR0 is set to the current or next instruction address. When rfi is executed, instruction execution continues at the address in SRR0.

```
<table>
<thead>
<tr>
<th>SRR1</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
</tr>
</tbody>
</table>
```

Figure 54. Save/Restore Register 1
Bits of SRR1 that correspond to reserved bits in the MSR are also reserved.

**Programming Note**

A MSR bit that is reserved may be inadvertently modified by \texttt{rfi/rfci/rfci}.  

The contents of SRR1 can be read into register RT using \texttt{mfspr RT,SRR1}. The contents of register RS can be written into the SRR1 using \texttt{mtspr SRR1,RS}.

This register is hypervisor privileged.

### 7.2.3 Guest Save/Restore Register 0 [Category:Embedded.Hypervisor]

Guest Save/Restore Register 0 (GSRR0) is a 64-bit register. GSRR0 bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on guest interrupts, and to restore machine state when an \texttt{rfi} is executed. On a guest interrupt, GSRR0 is set to the current or next instruction address. When \texttt{rfi} is executed, instruction execution continues at the address in GSRR0.

**Figure 55. Guest Save/Restore Register 0**

In general, GSRR0 contains the address of the instruction that caused the guest interrupt, or the address of the instruction to return to after a guest interrupt is serviced.

The contents of GSRR0 when an interrupt is taken are mode dependent, reflecting the computation mode currently in use (specified by MSR\textsubscript{CM}) and the computation mode entered for execution of the interrupt (specified by EPCR\textsubscript{GCM}). The contents of GSRR0 upon interrupt can be described as follows (assuming Addr is the address to be put into GSRR0):

\[
\begin{align*}
\text{if (MSR}_{\text{CM}} = 0) \& (\text{EPCR}_{\text{GCM}} = 0) & \text{ then GSRR0 } \leftarrow \text{undefined } || \text{Addr}_{32:63} \\
\text{if (MSR}_{\text{CM}} = 0) \& (\text{EPCR}_{\text{GCM}} = 1) & \text{ then GSRR0 } \leftarrow 0 || \text{Addr}_{32:63} \\
\text{if (MSR}_{\text{CM}} = 1) \& (\text{EPCR}_{\text{GCM}} = 1) & \text{ then GSRR0 } \leftarrow \text{Addr}_{0:63} \\
\text{if (MSR}_{\text{CM}} = 1) \& (\text{EPCR}_{\text{GCM}} = 0) & \text{ then GSRR0 } \leftarrow \text{undefined}
\end{align*}
\]

The contents of GSRR0 can be read into register RT using \texttt{mfspr RT,GSRR0}. The contents of register RS can be written into the GSRR0 using \texttt{mtspr GSRR0,RS}.

This register is privileged.

### 7.2.4 Guest Save/Restore Register 1 [Category:Embedded.Hypervisor]

Guest Save/Restore Register 1 (GSRR1) is a 32-bit register. GSRR1 bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on guest interrupts, and to restore machine state when an \texttt{rfgi} is executed. When a guest interrupt is taken, the contents of the MSR are placed into GSRR1. When \texttt{rfgi} is executed, the contents of GSRR1 are placed into the MSR.

**Figure 56. Guest Save/Restore Register 1**

Bits of GSRR1 that correspond to reserved bits in the MSR are also reserved.

**Programming Note**

A MSR bit that is reserved may be inadvertently modified by \texttt{rfi/rfgi/rfcf/rfci/rfmcf}.

The contents of GSRR1 can be read into register RT using \texttt{mfspr RT,GSRR1}. The contents of register RS can be written into the GSRR1 using \texttt{mtspr GSRR1,RS}.

This register is privileged.

### 7.2.5 Critical Save/Restore Register 0

Critical Save/Restore Register 0 (CSRR0) is a 64-bit register. CSRR0 bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on critical interrupts, and to restore machine state when an \texttt{rfci} is executed. When a critical interrupt is taken, the CSRR0 is set to the current or next instruction address. When \texttt{rfci} is executed,
instruction execution continues at the address in CSRR0.

Figure 57. Critical Save/Restore Register 0

In general, CSRR0 contains the address of the instruction that caused the critical interrupt, or the address of the instruction to return to after a critical interrupt is serviced.

The contents of CSRR0 when an interrupt is taken are mode dependent, reflecting the computation mode when the interrupt is taken and the computation mode entered for execution of the interrupt (specified by EPCR[ICM]) [Category:Embedded.Hypervisor]. If computation mode when the interrupt is taken is 32-bit mode and the computation mode entered for execution of the interrupt is 64-bit mode, the high-order 32 bits of CSRR0 are set to 0s. When computation mode when the interrupt is taken is 64-bit mode and the computation mode entered for execution of the interrupt is 32-bit mode, the contents CSRR0 are undefined.

The contents of CSRR0 upon critical interrupt can be described as follows (assuming Addr is the address to be put into CSRR0):

\[
\begin{align*}
\text{if } (\text{MSRCM} = 0) & \& (\text{EPCRICM} = 0) \text{ then } \text{CSRR0} \leftarrow 32\text{undefined} \parallel \text{Addr}_{32:63} \\
\text{if } (\text{MSRCM} = 0) & \& (\text{EPCRICM} = 1) \text{ then } \text{CSRR0} \leftarrow 320 \parallel \text{Addr}_{32:63} \\
\text{if } (\text{MSRCM} = 1) & \& (\text{EPCRICM} = 1) \text{ then } \text{CSRR0} \leftarrow \text{Addr}_{0:63} \\
\text{if } (\text{MSRCM} = 1) & \& (\text{EPCRICM} = 0) \text{ then } \text{CSRR0} \leftarrow \text{undefined}
\end{align*}
\]

The contents of CSRR0 can be read into register RT using \texttt{mfspr RT,CSRR0}. The contents of register RS can be written into CSRR0 using \texttt{mtspr CSRR0,RS}.

This register is hypervisor privileged.

7.2.6 Critical Save/Restore Register 1

Critical Save/Restore Register 1 (CSRR1) is a 32-bit register. CSRR1 bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The register is used to save machine state on critical interrupts, and to restore machine state when an \texttt{rfci} is executed. When a critical interrupt is taken, the contents of the MSR are placed into CSRR1. When \texttt{rfci} is executed, the contents of CSRR1 are placed into the MSR.

Figure 58. Critical Save/Restore Register 1

Bits of CSRR1 that correspond to reserved bits in the MSR are also reserved.

\[
\begin{align*}
\text{CSRR0} & \quad \parallel \\
0 & \quad 62 \ 63
\end{align*}
\]

\textbf{Programming Note}

A MSR bit that is reserved may be inadvertently modified by \texttt{rfi/rfci/rfmci}.

The contents of CSRR1 can be read into bits 32:63 of register RT using \texttt{mfspr RT,CSRR1}, setting bits 0:31 of RT to zero. The contents of bits 32:63 of register RS can be written into the CSRR1 using \texttt{mtspr CSRR1,RS}.

This register is hypervisor privileged.

7.2.7 Debug Save/Restore Register 0 [Category: Embedded.Enhanced Debug]

Debug Save/Restore Register 0 (DSRR0) is a 64-bit register used to save machine state on Debug interrupts, and to restore machine state when an \texttt{rdi} is executed. When a Debug interrupt is taken, the DSRR0 is set to the current or next instruction address. When \texttt{rdi} is executed, instruction execution continues at the address in DSRR0.

\[
\begin{align*}
\text{DSRR0} & \quad \parallel \\
0 & \quad 62 \ 63
\end{align*}
\]

Figure 59. Debug Save/Restore Register 0

In general, DSRR0 contains the address of an instruction that was executing or just finished execution when the Debug exception occurred.

The contents of DSRR0 when an interrupt is taken are mode dependent, reflecting the computation mode when the interrupt is taken and the computation mode entered for execution of the interrupt (specified by EPCR[ICM]) [Category:Embedded.Hypervisor]. If computation mode when the interrupt is taken is 32-bit mode and the computation mode entered for execution of the interrupt is 64-bit mode, the high-order 32 bits of DSRR0 are set to 0s. When computation mode when the interrupt is taken is 64-bit mode and the computation mode entered for execution of the interrupt is 32-bit mode, the contents DSRR0 are undefined.

The contents of DSRR0 upon Debug interrupt can be described as follows (assuming Addr is the address to be put into DSRR0):

\[
\begin{align*}
\text{if } (\text{MSRCM} = 0) & \& (\text{EPCRICM} = 0) \text{ then } \text{DSRR0} \leftarrow 32\text{undefined} \parallel \text{Addr}_{32:63} \\
\text{if } (\text{MSRCM} = 0) & \& (\text{EPCRICM} = 1) \text{ then } \text{DSRR0} \leftarrow 320 \parallel \text{Addr}_{32:63} \\
\text{if } (\text{MSRCM} = 1) & \& (\text{EPCRICM} = 1) \text{ then } \text{DSRR0} \leftarrow \text{Addr}_{0:63} \\
\text{if } (\text{MSRCM} = 1) & \& (\text{EPCRICM} = 0) \text{ then } \text{DSRR0} \leftarrow \text{undefined}
\end{align*}
\]

The contents of DSRR0 can be read into register RT using \texttt{mfspr RT,DSRR0}. The contents of register RS can be written into DSRR0 using \texttt{mtspr DSRR0,RS}.

This register is hypervisor privileged.
7.2.8 Debug Save/Restore Register 1 [Category: Embedded.Enhanced Debug]

Debug Save/Restore Register 1 (DSRR1) is a 32-bit register used to save machine state on Debug interrupts, and to restore machine state when an rfdi is executed. When a Debug interrupt is taken, the contents of the Machine State Register are placed into DSRR1. When rfdi is executed, the contents of DSRR1 are placed into the Machine State Register.

![Figure 60. Debug Save/Restore Register 1](image)

Bits of DSRR1 that correspond to reserved bits in the Machine State Register are also reserved.

The contents of DSRR1 can be read into bits 32:63 of register RT using mfspr RT,DSRR1, setting bits 0:31 of RT to zero. The contents of bits 32:63 of register RS can be written into the DSRR1 using mtspr DSRR1,RS.

This register is hypervisor privileged.

7.2.9 Data Exception Address Register

The Data Exception Address Register (DEAR) is a 64-bit register. DEAR bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The DEAR contains the address that was referenced by a Load, Store or Cache Management instruction that caused an Alignment, Data TLB Miss, or Data Storage interrupt if either the Embedded.Hypervisor category is not supported or the interrupt is directed to the hypervisor state. The DEAR is identical in form and function to DEAR.

The contents of the DEAR when an interrupt is taken are mode dependent, reflecting the computation mode currently in use (specified by MSR_CM) and the computation mode entered for execution of the interrupt (specified by EPCR_QICM). The contents of the DEAR upon interrupt can be described as follows (assuming Addr is the address to be put into GDEAR):

if (MSR_CM = 0) & (EPCR_QICM = 0)
then DEAR ← 32:undefined || Addr32:63
if (MSR_CM = 0) & (EPCR_QICM = 1)
then DEAR ← 32:0 || Addr32:63
if (MSR_CM = 1) & (EPCR_QICM = 1)
then DEAR ← Addr0:63
if (MSR_CM = 1)&(EPCR_QICM = 0)
then DEAR ← undefined

The contents of DEAR can be read into register RT using mfspr RT,DEAR. The contents of register RS can be written into the DEAR using mtspr DEAR,RS.

This register is privileged.

--- Programming Note ---

**mfspr RT,DEAR** should be used to read GDEAR in guest supervisor state. **mtspr DEAR,RS** should be used to write GDEAR in guest supervisor state. See Section 2.2.1, "Register Mapping".

7.2.10 Guest Data Exception Address Register [Category: Embedded.Hypervisor]

The Guest Data Exception Address Register (GDEAR) is a 64-bit register. GDEAR bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The GDEAR contains the address that was referenced by a Load, Store or Cache Management instruction that caused an Alignment, Data TLB Miss, or Data Storage interrupt that was directed to the guest supervisor state. The GDEAR is identical in form and function to DEAR.

The contents of the GDEAR when an interrupt is taken are mode dependent, reflecting the computation mode currently in use (specified by MSR_CM) and the computation mode entered for execution of the interrupt (specified by EPCR_QICM). The contents of the GDEAR upon interrupt can be described as follows (assuming Addr is the address to be put into GDEAR):

if (MSR_CM = 0) & (EPCR_QICM = 0)
then GDEAR ← 32:undefined || Addr32:63
if (MSR_CM = 0) & (EPCR_QICM = 1)
then GDEAR ← 32:0 || Addr32:63
if (MSR_CM = 1) & (EPCR_QICM = 1)
then GDEAR ← Addr0:63
if (MSR_CM = 1)&(EPCR_QICM = 0)
then GDEAR ← undefined

The contents of GDEAR can be read into register RT using mfspr RT,GDEAR. The contents of register RS can be written into the GDEAR using mtspr GDEAR,RS.

This register is privileged.

7.2.11 Interrupt Vector Prefix Register

The Interrupt Vector Prefix Register (IVPR) is a 64-bit register. Interrupt Vector Prefix Register bits are numbered 0 (most-significant bit) to 63 (least-significant bit). The IVPR is used for Machine Check interrupt if the MCIVPR is not supported. The IVPR is used for other interrupts if Category E.HV is not supported or if the interrupt is directed to the hypervisor state. For these interrupts, the IVPR is used in one of the following ways.

- If Interrupt Vector Offset Registers [Category: Embedded.Phased-Out] are supported, the following applies. Bits 48:63 are reserved. Bits 0:47 of...
the Interrupt Vector Prefix Register provide the high-order 48 bits of the address of the exception processing routines. The 16-bit exception vector offsets from the appropriate IVOR (provided in Section 7.6.1, "Interrupt Fixed Offsets [Category: Embedded.Phased-In]") are concatenated to the right of bits 0:47 of the Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, the following applies. IVPR[52:63] are reserved. Bits 0:51 of the Interrupt Vector Prefix Register provide the high-order 52 bits of the address of the exception processing routines. The 12-bit exception vector offsets (provided in Section 7.6.1, "Interrupt Fixed Offsets [Category: Embedded.Phased-In]") are concatenated to the right of bits 0:47 of the Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.

The contents of Interrupt Vector Prefix Register can be read into register RT using mfspr RT,IVPR. The contents of register RS can be written into Interrupt Vector Prefix Register using mtspr IVPR,RS. This register is hypervisor privileged.

7.2.12 Guest Interrupt Vector Prefix Register [Category: Embedded.Hypervisor]

The Guest Interrupt Vector Prefix Register (GIVPR) is a 64-bit register. Interrupt Vector Prefix Register bits are numbered 0 (most-significant bit) to 63 (least-significant bit).

If Interrupt Vector Offset Registers [Category: Embedded.Phased-Out] are supported, the following applies. GIVPR[48:63] are reserved. For interrupts directed to guest state, bits 0:47 of the Guest Interrupt Vector Prefix Register provides the high-order 48 bits of the address of the exception processing routines. The 16-bit exception vector offsets (provided in Section 7.6.1, "Interrupt Fixed Offsets [Category: Embedded.Phased-In]") are concatenated to the right of bits 0:47 of the Guest Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, the following applies. GIVPR[52:63] are reserved. For interrupts directed to guest state, bits 0:51 of the Guest Interrupt Vector Prefix Register provide the high-order 52 bits of the address of the exception processing routines. The 12-bit exception vector offsets (provided in Section 7.6.1, "Interrupt Fixed Offsets [Category: Embedded.Phased-In]") are concatenated to the right of bits 0:47 of the Guest Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.

The contents of Guest Interrupt Vector Prefix Register can be read into register RT using mfspr RT,GIVPR. The contents of register RS can be written into Interrupt Vector Prefix Register using mtspr GIVPR,RS. Write access to this register is hypervisor privileged. Read access to this register is privileged.

Programming Note

mfspr RT,IVPR should be used to read GIVPR in guest supervisor state. mtspr IVPR,RS should be used to write GIVPR in guest supervisor state. Hypervisor software should emulate the accesses for the guest.
### 7.2.13 Exception Syndrome Register

The Exception Syndrome Register (ESR) is a 32-bit register. ESR bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The ESR provides a *syndrome* to differentiate between the different kinds of exceptions that can generate the same interrupt type. Upon the generation of one of these types of interrupts, the bit or bits corresponding to the specific exception that generated the interrupt is set, and all other ESR bits are cleared. Other interrupt types do not affect the contents of the ESR. The ESR does not need to be cleared by software. Figure 61 shows the bit definitions for the ESR.

Programming Note

The information provided by the ESR is not complete. System software may also need to identify the type of instruction that caused the interrupt, examine the TLB entry accessed by a data or instruction storage access, as well as examine the ESR to fully determine what exception or exceptions caused the interrupt. For example, a Data Storage interrupt may be caused by both a Protection Violation exception as well as a Byte Ordering exception. System software would have to look beyond ESRBO, such as the state of MSRPR in SRR1 and the page protection bits in the TLB entry accessed by the storage access, to determine whether or not a Protection Violation also occurred.

The contents of the ESR can be read into bits 32:63 of register RT using `mfspr RT,ESR`, setting bits 0:31 of RT to zero. The contents of bits 32:63 of register RS can be written into the ESR using `mtspr ESR,RS`.

This register is hypervisor privileged.

7.2.14 Guest Exception Syndrome Register [Category: Embedded.Hypervisor]

The Guest Exception Syndrome Register (GESR) is a 32-bit register. GESR bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The GESR is identical in form and function to the ESR, but is updated in place of the ESR when an interrupt is directed to the guest. For a description of bit settings and meanings see Section 7.2.13, "Exception Syndrome Register".

The contents of the GESR can be read into bits 32:63 of register RT using `mfspr RT,GESR`, setting bits 0:31 of RT to zero. The contents of bits 32:63 of register RS can be written into the GESR using `mtspr GESR,RS`.

This register is privileged.

Programming Note

`mfspr RT,ESR` should be used to read GESR in guest supervisor state. `mtspr ESR,RS` should be used to write GESR in guest supervisor state. See Section 2.2.1, "Register Mapping".

7.2.15 Interrupt Vector Offset Registers [Category: Embedded.Phased-Out]

The Interrupt Vector Prefix Register (IVPR) is a 64-bit register. Interrupt Vector Prefix Register bits are numbered 0 (most-significant bit) to 63 (least-significant bit).

The IVPR is used for Machine Check interrupt if the MCIIVPR is not supported. The IVPR is used for other interrupts if Category E.HV is not supported or if the interrupt is directed to the hypervisor state. For these interrupts, the IVPR is used in one of the following ways.

- If Interrupt Vector Offset Registers [Category: Embedded.Phased-Out] are supported, the following applies. Bits 48:63 are reserved. Bits 0:47 of the Interrupt Vector Prefix Register provide the high-order 48 bits of the address of the exception processing routines. The 16-bit exception vector offsets from the appropriate IVOR (provided in Section 7.2.15) are concatenated to the right of bits 0:47 of the Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.

- If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, the following applies. IVPR52:63 are reserved. Bits 0:51 of the Interrupt Vector Prefix Register provide the high-order 52 bits of the address of the exception processing routines. The 12-bit exception vector offsets (provided in Section 7.2.15) are concatenated to the right of bits 0:47 of the Interrupt Vector Prefix Register to form the 64-bit address of the exception processing routine.
Figure 62. Interrupt Vector Offset Register Assignments

Bits 48:59 of the contents of IVORi can be read into bits 48:59 of register RT using \texttt{mfspr RT,IVORi}, setting bits 0:47 and bits 60:63 of GPR(RT) to zero. Bits 48:59 of the contents of register RS can be written into bits 48:59 of IVORi using \texttt{mtspr IVORi,RS}.

These registers are hypervisor privileged.

\subsection*{7.2.16 Guest Interrupt Vector Offset Register} [Category: Embedded.Hypervisor.Phased-Out]

The Guest Interrupt Vector Offset Registers (GIVORs) are 32-bit registers. Guest Interrupt Vector Offset Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). Bits 32:47 and bits 60:63 are reserved. A Guest Interrupt Vector Offset Register provides the quadword index from the base address provided by the GIVPR (see Section 7.2.12) for its respective guest state interrupt. Guest Interrupt Vector Offset Registers are analogous to Interrupt Vector Offset Registers except that they are used when an interrupt is directed to the guest supervisor state. Figure 63 provides the assignments of specific Guest Interrupt Vector Offset Registers to specific interrupts.

Figure 63. Guest Interrupt Vector Offset Register Assignments

Bits 48:59 of the contents of GIVORi can be read into bits 48:59 of register RT using \texttt{mfspr RT,GIVORi}, setting bits 0:47 and bits 60:63 of GPR(RT) to zero. Bits 48:59 of the contents of register RS can be written into bits 48:59 of GIVORi using \texttt{mtspr GIVORi,RS}.

Write access to these registers is hypervisor privileged. Read access to these registers is privileged.
7.2.17 Logical Page Exception Register [Category: Embedded.Hypervisor and Embedded.Page Table]

The Logical Page Exception Register (LPER) is a 64-bit register that is required when both the Embedded.Hypervisor and Embedded.Page Table categories are supported. LPER bits are numbered 0 (most-significant bit) to 63 (least-significant bit).

The LPER fields are described below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>12:52</td>
<td>Abbreviated Logical Page Number (ALPN)</td>
</tr>
<tr>
<td></td>
<td>This field contains the Abbreviated Real Page Number from the PTE which caused the LRAT Error interrupt. Only bits corresponding to the PTE_ARPN bits supported by the implementation need be implemented.</td>
</tr>
<tr>
<td>60:63</td>
<td>Logical Page Size (LPS)</td>
</tr>
<tr>
<td></td>
<td>This field contains the Page Size from the PTE that caused the LRAT Error interrupt.</td>
</tr>
</tbody>
</table>

All other fields are reserved.

The LPER contains the values of the ARPN and PS fields from the PTE that was used to translate a virtual address for an instruction fetch, Load, Store or Cache Management instruction that caused an LRAT Error interrupt as a result of an LRAT Miss exception. The contents of LPER are unchanged by an interrupt for any other type of exception.

The LPER is a hypervisor resource.

The contents of the Logical Page Exception Register can be read into register RT using mfspr RT,LPER. The contents of register RS can be written into the LPER using mtspr LPER,RS. On both a 32-bit and a 64-bit implementation, the contents of register RS_{32:63} can be written into the LPER_{0:31} using mtspr LPERU,RS.

On a 32-bit implementation that supports fewer than 33 bits of real address, it is implementation-dependent whether the SPR number for LPERU is treated as a reserved value for mfspr and mtspr.

The LPER is a hypervisor resource.

7.2.18 Machine Check Registers

A set of Special Purpose Registers are provided to support Machine Check interrupts.

7.2.18.1 Machine Check Save/Restore Register 0

Machine Check Save/Restore Register 0 (MCSRR0) is a 64-bit register used to save machine state on Machine Check interrupts, and to restore machine state when an rfmc i is executed. When a Machine Check interrupt is taken, the MCSRR0 is set to the current or next instruction address. When rfmc i is executed, instruction execution continues at the address in MCSRR0.

The contents of MCSRR0 when a Machine Check interrupt is taken are mode dependent, reflecting the computation mode currently in use (specified by MSR_CM) and the computation mode entered for execution of the Machine Check interrupt (specified by EPCR_CM) [Category:Embedded.Hypervisor]. The contents of MCSRR0 upon Machine Check interrupt can be described as follows (assuming Addr is the address to be put into MCSRR0):

if (MSR_CM = 0) & (EPCR_CM = 0) then MCSRR0 ← 32undefined || Addr_{32:63}
if (MSR_CM = 0) & (EPCR_CM = 1) then MCSRR0 ← 320 || Addr_{32:63}
if (MSR_CM = 1) & (EPCR_CM = 1) then MCSRR0 ← Addr_{0:63}
if (MSR_CM = 1) & (EPCR_CM = 0) then MCSRR0 ← undefined

The contents of MCSRR0 can be read into register RT using mfspr RT,MCSRR0. The contents of register RS can be written into MCSRR0 using mtspr MCSRR0,RS.

This register is hypervisor privileged.

---

**Programming Note**

mfspr RT,IVORi should be used to read GIVORi in guest supervisor state. mtspr IVORi,RS should be used to write GIVOR in guest supervisor state. Hypervisor software should emulate the accesses for the guest.

**Programming Note**

The architecture only provides a few GIVORs that are implemented in hardware that are performance critical. Hypervisor software should emulate access to IVORs that do not have corresponding GIVORs.
7.2.18.2 Machine Check Save/Restore Register 1

Machine Check Save/Restore Register 1 (MCSRR1) is a 32-bit register used to save machine state on Machine Check interrupts, and to restore machine state when an rfmc1i is executed. When a Machine Check interrupt is taken, the contents of the MSR are placed into MCSRR1. When rfmc1i is executed, the contents of MCSRR1 are placed into the MSR.

Bits of MCSRR1 that correspond to reserved bits in the MSR are also reserved.

Figure 66. Machine Check Save/Restore Register 1

The contents of MCSRR1 can be read into register RT using mfspr RT,MCSRR1. The contents of register RS can be written into the MCSRR1 using mtspr MCSRR1,RS.

This register is hypervisor privileged.

7.2.18.3 Machine Check Syndrome Register

MCSR (MCSR) is a 64-bit register that is used to record the cause of the Machine Check interrupt. The specific definition of the contents of this register are implementation-dependent (see the User Manual of the implementation).

The contents of MCSR can be read into register RT using mfspr RT,MCSR. The contents of register RS can be written into the MCSR using mtspr MCSR,RS.

This register is hypervisor privileged.

7.2.18.4 Machine Check Interrupt Vector Prefix Register

The Machine Check Interrupt Vector Prefix Register (MCIVPR) is a 64-bit register. MCIVPR is supported only if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported. Whether the MCIVPR is supported is implementation-dependent.

Machine Check Interrupt Vector Prefix Register bits are numbered 0 (most-significant bit) to 63 (least-significant bit). MCIVPR[52:63] are reserved. Bits 0:51 of the Machine Check Interrupt Vector Prefix Register provide the high-order 52 bits of the address of the Machine Check exception processing routine. The 12-bit Machine Check exception vector offset (provided in Section 7.2.15) is concatenated to the right of bits 0:47 of the Machine Check Interrupt Vector Prefix Register to form the 64-bit address of the Machine Check exception processing routine.

The contents of Machine Check Interrupt Vector Prefix Register can be read into register RT using mfspr RT,IVPR. The contents of register RS can be written into Machine Check Interrupt Vector Prefix Register using mtspr IVPR,RS.

Program Note
In some implementations that support Interrupt Fixed Offsets, certain instruction cache errors result in a Machine Check exception. The Machine Check interrupt handler needs to be in Caching Inhibited storage in order for the interrupt handler to operate despite an instruction cache error.

7.2.19 External Proxy Register

[Category: External Proxy]

The External Proxy Register (EPR) contains implementation-dependent information related to an External Input interrupt when an External Input interrupt occurs. The EPR is only considered valid from the time that the External Input Interrupt occurs until MSR[EE] is set to 1 as the result of a mtmsr or a return from interrupt instruction.

The format of the EPR is shown below.

Figure 67. External Proxy Register

When the External Input interrupt is taken, the contents of the EPR provide information related to the External Input Interrupt.

This register is hypervisor privileged.

Program Note
The EPR is provided for faster interrupt processing as well as situations where an interrupt must be taken, but software must delay the resultant processing for later.

The EPR contains the vector from the interrupt controller. The process of receiving the interrupt into the EPR acknowledges the interrupt to the interrupt controller. The method for enabling or disabling the acknowledgment of the interrupt by placing the interrupt-related information in the EPR is implementation-dependent. If this acknowledgement is disabled, then the EPR is set to 0 when the External Input interrupt occurs.
7.2.20 Guest External Proxy Register [Category: Embedded Hypervisor, External Proxy]

The Guest External Proxy Register (GEPR) contains implementation-dependent information related to an External Input interrupt when an External Input interrupt directed to the guest occurs. The GEPR is only considered valid from the time that the External Input Interrupt occurs until MSR_EE is set to 1 as the result of a `mtmsr` or a return from interrupt instruction.

The format of the GEPR is shown below.

![GEPR Format](image)

Figure 68. Guest External Proxy Register

When the External Input interrupt is taken in the guest supervisor state, the contents of the GEPR provide information related to the External Input Interrupt.

The contents of the GEPR can be read into bits 32:63 of register RT using `mfspr RT,GEPR`, setting bits 0:31 of RT to zero. The contents of bits 32:63 of register RS can be written into the GEPR using `mtspr GEPR,RS`.

The GEPR is identical in form and function to the EPR.

This register is privileged.

---

**Programming Note**

Writing the GEPR register is allowed from both guest supervisor state and hypervisor state. Hypervisor must be able to write GEPR to virtualize External Input interrupt handling for the guest if the guest is using External Proxy. Writing to EPR from the guest is not mapped and results in the same behavior as any undefined supervisor level SPR.

---

**Programming Note**

The GEPR is provided for faster interrupt processing as well as situations where an interrupt must be taken, but software must delay the resultant processing for later.

The GEPR contains the vector from the interrupt controller. The process of receiving the interrupt into the GEPR acknowledges the interrupt to the interrupt controller. The method for enabling or disabling the acknowledgment of the interrupt by placing the interrupt-related information in the GEPR is implementation-dependent. If this acknowledgement is disabled, then the GEPR is set to 0 when the External Input interrupt occurs.

**Programming Note**

`mfspr RT,EPR` should be used to read GEPR in guest supervisor state. Hypervisor software should emulate the accesses for the guest. This keeps the programming model consistent for an operating system running as a guest and running directly in hypervisor state.
7.3 Exceptions

There are two kinds of exceptions, those caused directly by the execution of an instruction and those caused by an asynchronous event. In either case, the exception may cause one of several types of interrupts to be invoked.

Examples of exceptions that can be caused directly by the execution of an instruction include but are not limited to the following:

- an attempt to execute a reserved-illegal instruction (Illegal Instruction exception type Program interrupt)
- an attempt by an application program to execute a "privileged" instruction (Privileged Instruction exception type Program interrupt)
- an attempt by an application program to access a "privileged" Special Purpose Register (Privileged Instruction exception type Program interrupt)
- an attempt by an application program to access a Special Purpose Register that does not exist (Unimplemented Operation Instruction exception type Program interrupt)
- an attempt by a system program to access a Special Purpose Register that does not exist (boundedly undefined results)
- the execution of a defined instruction using an invalid form (Illegal Instruction exception type Program interrupt, Unimplemented Operation exception type Program interrupt, or Privileged Instruction exception type Program interrupt)
- an attempt to access a storage location that is either unavailable (Instruction TLB Error interrupt or Data TLB Error interrupt) or not permitted (Instruction Storage interrupt or Data Storage interrupt)
- an attempt to access storage with an effective address alignment not supported by the implementation (Alignment interrupt)
- the execution of a System Call instruction (System Call interrupt)
- the execution of a Trap instruction whose trap condition is met (Trap type Program interrupt)
- the execution of a floating-point instruction when floating-point instructions are unavailable (Floating-point Unavailable interrupt)
- the execution of a floating-point instruction that causes a floating-point enabled exception to exist (Enabled exception type Program interrupt)
- the execution of a defined instruction that is not implemented by the implementation (Illegal Instruction exception or Unimplemented Operation exception type of Program interrupt)
- the execution of an instruction that is not implemented by the implementation (Illegal Instruction exception or Unimplemented Operation exception type of Program interrupt)
- the execution of an auxiliary processor instruction when the auxiliary processor instruction is unavailable (Auxiliary Processor Unavailable interrupt)
- the execution of an instruction that causes an auxiliary processor enabled exception (Enabled exception type Program interrupt)

The invocation of an interrupt is precise, except that if one of the imprecise modes for invoking the Floating-point Enabled Exception type Program interrupt is in effect then the invocation of the Floating-point Enabled Exception type Program interrupt may be imprecise. When the interrupt is invoked imprecisely, the excepting instruction does not appear to complete before the next instruction starts (because one of the effects of the excepting instruction, namely the invocation of the interrupt, has not yet occurred).

7.4 Interrupt Classification

All interrupts, except for Machine Check, can be classified as either Asynchronous or Synchronous. Independent from this classification, all interrupts, including Machine Check, can be classified into one of the following classes:

- Guest [Category:Embedded.Hypervisor]
- Base
- Critical
- Machine Check
- Debug[Category:Embedded.Enhanced Debug].

7.4.1 Asynchronous Interrupts

Asynchronous interrupts are caused by events that are independent of instruction execution. For asynchronous interrupts, the address reported to the exception handling routine is the address of the instruction that would have executed next, had the asynchronous interrupt not occurred.

7.4.2 Synchronous Interrupts

Synchronous interrupts are those that are caused directly by the execution (or attempted execution) of instructions, and are further divided into two classes, precise and imprecise.

Synchronous, precise interrupts are those that precisely indicate the address of the instruction causing the exception that generated the interrupt; or, for certain synchronous, precise interrupt types, the address of the immediately following instruction.

Synchronous, imprecise interrupts are those that may indicate the address of the instruction causing the
exception that generated the interrupt, or some instruction after the instruction causing the exception.

### 7.4.2.1 Synchronous, Precise Interrupts

When the execution or attempted execution of an instruction causes a synchronous, precise interrupt, the following conditions exist at the interrupt point.

- **GSRR0** [Category: Embedded.Hypervisor], **SRR0**, **CSR0**, or **DSRR0** [Category: Embedded.Enhanced Debug] addresses either the instruction causing the exception or the instruction immediately following the instruction causing the exception. Which instruction is addressed can be determined from the interrupt type and status bits.

- An interrupt is generated such that all instructions preceding the instruction causing the exception appear to have completed with respect to the executing thread. However, some storage accesses associated with these preceding instructions may not have been performed with respect to other threads and mechanisms.

- The instruction causing the exception may appear not to have begun execution (except for causing the exception), may have been partially executed, or may have completed, depending on the interrupt type. See Section 7.7 on page 1186.

- Architecturally, no subsequent instruction has executed beyond the instruction causing the exception.

### 7.4.2.2 Synchronous, Imprecise Interrupts

When the execution or attempted execution of an instruction causes an imprecise interrupt, the following conditions exist at the interrupt point.

When the execution or attempted execution of an instruction causes an imprecise interrupt, the following conditions exist at the interrupt point.

- **GSRR0** [Category: Embedded.Hypervisor], **SRR0**, or **CSR0** addresses either the instruction causing the exception or some instruction following the instruction causing the exception that generated the interrupt.

- An interrupt is generated such that all instructions preceding the instruction addressed by GSRR0 [Category: Embedded.Hypervisor], SRR0, or CSR0 appear to have completed with respect to the executing thread.

- If the imprecise interrupt is forced by the context synchronizing mechanism, due to an instruction that causes another exception that generates an interrupt (e.g., Alignment, Data Storage), then **GSRR0** [Category: Embedded.Hypervisor] or **SRR0** addresses the interrupt-forcing instruction, and the interrupt-forcing instruction may have been partially executed (see Section 7.7 on page 1186).

- If the imprecise interrupt is forced by the execution synchronizing mechanism, due to executing an execution synchronizing instruction other than **sync** or **isync**, then GSRR0 [Category: Embedded.Hypervisor], SRR0, or CSR0 addresses the interrupt-forcing instruction, and the interrupt-forcing instruction appears not to have begun execution (except for its forcing the imprecise interrupt). If the imprecise interrupt is forced by an **sync** or **isync** instruction, then GSRR0 [Category: Embedded.Hypervisor], SRR0, or CSR0 may address either the **sync** or **isync** instruction, or the following instruction.

- If the imprecise interrupt is not forced by either the context synchronizing mechanism or the execution synchronizing mechanism, then the instruction addressed by GSRR0 [Category: Embedded.Hypervisor], SRR0, or CSR0 may have been partially executed (see Section 7.7 on page 1186).

- No instruction following the instruction addressed by GSRR0 [Category: Embedded.Hypervisor], SRR0, or CSR0 has executed.

### 7.4.3 Interrupt Classes

Interrupts can also be classified as guest [Category: Embedded.Hypervisor], base, critical, Machine Check, and Debug [Category: Embedded.Enhanced Debug].

Interrupt classes other than the guest [Category: Embedded.Hypervisor] or base class may demand immediate attention even if another class of interrupt is currently being processed and software has not yet had the opportunity to save the state of the machine (i.e. return address and captured state of the MSR). For this reason, the interrupts are organized into a hierarchy (see Section 7.8). To enable taking a critical, Machine Check, or Debug [Category: Embedded.Enhanced Debug] interrupt immediately after a guest [Category: Embedded.Hypervisor] or base class interrupt occurs (i.e. before software has saved the state of the machine), these interrupts use the Save/Restore Register pair **CSRR0/CSR1**, **MCSRR0/MCSRR1**, or **DSRR0/DSRR1** [Category: Embedded.Enhanced Debug], and guest [Category: Embedded.Hypervisor] and base class interrupts use Save/Restore Register pairs **GSRR0/GSRR1** and **SRR0/SRR1** respectively.

### 7.4.4 Machine Check Interrupts

Machine Check interrupts are a special case. They are typically caused by some kind of hardware or storage subsystem failure, or by an attempt to access an invalid address. A Machine Check may be caused indirectly by the execution of an instruction, but not be recognized and/or reported until long after the thread has executed.
past the instruction that caused the Machine Check. As such, Machine Check interrupts cannot properly be thought of as synchronous or asynchronous, nor as precise or imprecise. The following general rules apply to Machine Check interrupts:

1. No instruction after the one whose address is reported to the Machine Check interrupt handler in MCSRR0 has begun execution.

2. The instruction whose address is reported to the Machine Check interrupt handler in MCSRR0, and all prior instructions, may or may not have completed successfully. All those instructions that are ever going to complete appear to have done so already, and have done so within the context existing prior to the Machine Check interrupt. No further interrupt (other than possible additional Machine Check interrupts) will occur as a result of those instructions.

### 7.5 Interrupt Processing

Associated with each kind of interrupt is an interrupt vector, that is the address of the initial instruction that is executed when the corresponding interrupt occurs.

When Category: Embedded.Hypervisor is implemented, interrupts are directed (see Section 2.3.1, “Directed Interrupts”) to the guest supervisor state or the hypervisor state, which effects how some MSR bits are set. The conditions under which a given interrupt is directed to the guest supervisor state or hypervisor state is more fully described in the interrupt definitions for each interrupt in Section 7.6, “Interrupt Definitions”.

Interrupt processing consists of saving a small part of the thread's state in certain registers, identifying the cause of the interrupt in another register, and continuing execution at the corresponding interrupt vector location. When an exception exists that will cause an interrupt to be generated and it has been determined that the interrupt can be taken, the following actions are performed, in order:

1. GSRR0 [Category: Embedded.Hypervisor], SRR0, DSRR0 [Category: Embedded.Enhanced Debug], MCSRR0, or CSRR0 is loaded with an instruction address that depends on the interrupt; see the specific interrupt description for details.

2. The GESR [Category: Embedded.Hypervisor] or ESR is loaded with information specific to the exception. Note that many interrupts can only be caused by a single kind of exception event, and thus do not need nor use an ESR setting to indicate to the cause of the interrupt was.

3. GSRR1 [Category: Embedded.Hypervisor], SRR1, DSRR1 [Category: Embedded.Enhanced Debug], or MCSRR1, or CSRR1 is loaded with a copy of the contents of the MSR.

4. The MSR is updated as described below. The new values take effect beginning with the first instruction following the interrupt. MSR bits of particular interest are the following.
   - MSR_PEE,PR,PF,FE,IS,DS,SPV are set to 0 by all interrupts.
   - If Category E.HV is supported, MSR_GS is left unchanged when an interrupt is directed to the guest supervisor state, otherwise they are set to 0 by all interrupts.
   - If Category E.HV is supported, MSR_PPM is left unchanged when an interrupt is directed to the guest supervisor state and MSR_PPMP = 1, otherwise MSR_PPM is set to 0 by all interrupts.
   - If Category E.HV is supported, MSR_UCLE is left unchanged when an interrupt is directed to the guest supervisor state and MSR_UCLEP = 1, otherwise MSR_UCLE is set to 0 by all interrupts.
   - MSR_ME is set to 0 by Machine Check interrupts and left unchanged by all other interrupts.
   - MSR_CE is set to 0 by critical class interrupts, Debug interrupts, and Machine Check interrupts, and is left unchanged by all other interrupts.
   - MSR_DIE is set to 0 by critical class interrupts unless Category E.ED is supported, by Debug interrupts, and by Machine Check interrupts, and is left unchanged by all other interrupts.
   - If Category E.HV is supported and the interrupt is directed to the guest supervisor state, MSR_CM is set to EPCR_GICM, otherwise MSR_CM is set to EPCR_ICM.
   - Other supported MSR bits are left unchanged by all interrupts.

See Section 4.2.1 for more detail on the definition of the MSR.

5. Instruction fetching and execution resumes, using the new MSR value, at a location specific to the interrupt. If Category E.HV is supported, and the interrupt is directed to the guest state, the location is one of the following, where IVORi (GIVORi) is the (Guest) Interrupt Vector Offset Register for that interrupt (see Figure 63 on page 1152):
   - GIVPR[0:47] || GIVOR[48:59] || 0b0000 if Interrupt Vector Offset Registers [Category: Embedded.Phased-Out] are supported
   - GIVPR[0:51] || fixed offset shown in Figure Figure 62 on page 1152 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported

Otherwise, the location is one of the following:
   - IVPR[0:47] || IVOR[48:59] || 0b0000 if Interrupt Vector Offset Registers [Category: Embedded.Phased-Out] are supported
IVPR0..51 || fixed offset shown in Figure Figure 62 on page 1152 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported and either MCIVPR is not supported or the interrupt is not a Machine Check

MCIVPR0..51 || fixed offset shown in Figure Figure 70 on page 1165 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, MCIVPR is supported, and the interrupt is a Machine Check

The contents of the (Guest) Interrupt Vector Prefix Register, Machine Check Interrupt Vector Prefix Register, and (Guest) Interrupt Vector Offset Registers are indeterminate upon power-on reset, and must be initialized by system software using the \texttt{mtspr} instruction.

It is implementation-dependent whether interrupts clear reservations obtained with \texttt{lbarx}, \texttt{lharx}, \texttt{lwarx}, \texttt{ldarx}, or \texttt{lqarx}.

Interrupts might not clear reservations obtained with \texttt{Load and Reserve} instructions. The operating system or hypervisor should do so at appropriate points, such as at process switch or a partition switch.

At the end of an interrupt handling routine, execution of an \texttt{rfgi} [Category: Embedded.Hypervisor], \texttt{rfi}, \texttt{rfdi} [Category: Embedded.Enhanced Debug], \texttt{rfmci}, or \texttt{rfci} causes the MSR to be restored from the contents of GSRR1 [Category: Embedded.Hypervisor], SRR1, DSRR1 [Category: Embedded.Enhanced Debug], MCSRR1, or CSRR1, and instruction execution to resume at the address contained in GSRR0 [Category: Embedded.Hypervisor], SRR0, DSRR0 [Category: Embedded.Enhanced Debug], MCSRR0, or CSRR0, respectively.

**Programming Note**

In general, at process switch (partition switch), due to possible process interlocks and possible data availability requirements, the operating system (hypervisor) needs to consider executing the following.

- \texttt{stbcx, sthcx, stwcx, stdcx,} or \texttt{stqcx}, to clear the reservation if one is outstanding, to ensure that a \texttt{lbarx}, \texttt{lharx}, \texttt{lwarx}, \texttt{ldarx}, or \texttt{lqarx} in the “old” process (partition) is not paired with a \texttt{stbcx}, \texttt{sthcx}, \texttt{stwcx}, \texttt{stdcx}, or \texttt{stqcx} in the “new” process (partition).

- \texttt{sync}, to ensure that all storage operations of an interrupted process are complete with respect to other threads before that process begins executing on another thread.

- \texttt{isync}, \texttt{rfgi <E.HV>, rfi, rfdi} [Category: Embedded.Enhanced Debug], \texttt{rfmci}, or \texttt{rfci} to ensure that the instructions in the “new” process execute in the “new” context.
Programming Note

For instruction-caused interrupts, in some cases it may be desirable for the operating system to emulate the instruction that caused the interrupt, while in other cases it may be desirable for the operating system not to emulate the instruction. The following list, while not complete, illustrates criteria by which decisions regarding emulation should be made. The list applies to general execution environments; it does not necessarily apply to special environments such as program debugging, bring-up, etc.

In general, the instruction should be emulated if:
- The interrupt is caused by a condition for which the instruction description (including related material such as the introduction to the section describing the instruction) implies that the instruction works correctly. Example: Alignment interrupt caused by `lmw` for which the storage operand is not aligned, or by `dcbz` or `dcbzep` for which the storage operand is in storage that is Write Through Required or Caching Inhibited.
- The instruction is an illegal instruction that should appear, to the program executing it, as if it were supported by the implementation. Example: Illegal Instruction type Program interrupt caused by an instruction that has been phased out of the architecture but is still used by some programs that the operating system supports, or by an instruction that is in a category that the implementation does not support but is used by some programs that the operating system supports.

In general, the instruction should not be emulated if:
- The purpose of the instruction is to cause an interrupt. Example: System Call interrupt caused by `sc`.
- The interrupt is caused by a condition that is stated, in the instruction description, potentially to cause the interrupt. Example: Alignment interrupt caused by `lwarx` for which the storage operand is not aligned.
- The program is attempting to perform a function that it should not be permitted to perform. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should not be permitted to access. (If the function is one that the program should be permitted to perform, the conditions that caused the interrupt should be corrected and the program re-dispatched such that the instruction will be re-executed. Example: Data Storage interrupt caused by `lwz` for which the storage operand is in storage that the program should be permitted to access but for which there currently is no TLB entry.)
## 7.6 Interrupt Definitions

Table 69 provides a summary of each interrupt type, the various exception types that may cause that interrupt type, the classification of the interrupt, which ESR (GESR) bits can be set, if any, which MSR bits can mask the interrupt type and which Interrupt Vector Offset Register is used to specify that interrupt type’s vector address.

</table>
1. If an expression of MSR bits is provided, the interrupt is masked if the expression evaluates to 0 and is enabled if the expression evaluates to 1.

Figure 69. Interrupt and Exception Types

Figure 69 Notes

1. Although it is not specified, it is common for system implementations to provide, as part of the interrupt controller, independent mask and status bits for the various sources of Critical Input and External Input interrupts.

2. Machine Check interrupts are a special case and are not classified as asynchronous nor synchronous. See Section 7.4.4 on page 1157.

3. The Instruction Complete and Branch Taken debug events are only defined for MSRDE=1 when in Internal Debug Mode (DBCR0DM=1). In other words, when in Internal Debug Mode with MSRDE=0, then Instruction Complete and Branch Taken debug events cannot occur, and no DBSR status bits are set and no subsequent imprecise Debug interrupt will occur (see Section 10.4 on page 1213).

4. Machine Check status information is commonly provided as part of the system implementation, but is implementation-dependent.

5. In general, when an interrupt causes a particular ESR (GESR) bit or bits to be set (or cleared) as indicated in the table, it also causes all other ESR (GESR) bits to be cleared. There may be special rules regarding the handling of implementation-specific ESR (GESR) bits.

   Legend:
   
   \[ \text{[xxx]} \] means ESR(GESR)\_xxx could be set
   \[ \text{[xxx,yyy]} \] means either ESR(GESR)\_xxx or ESR(GESR)\_yyy may be set, but never both
   \[ \text{(xxx,yyy)} \] means either ESR(GESR)\_xxx or ESR(GESR)\_yyy will be set, but never both
   \[ \text{(xxx,yyy)} \] means either ESR(GESR)\_xxx or ESR(GESR)\_yyy will be set, or possibly both
   xxx means ESR(GESR)\_xxx is set

6. The precision of the Floating-point Enabled Exception type Program interrupt is controlled by the MSR\_\text{FE}_0,\text{FE}_1 bits. When MSR\_\text{FE}_0,\text{FE}_1=0b01 or 0b10, the interrupt may be imprecise. When such a Program interrupt is taken, if the address saved in SRR0 is not the address of the instruction that caused the exception (i.e. the instruction that caused FPSCR\_\text{FE}X to be set to 1), ESR\_\text{PIE} is set to 1. When MSR\_\text{FE}_0,\text{FE}_1=0b11, the interrupt is precise. When MSR\_\text{FE}_0,\text{FE}_1=0b00, the interrupt is masked, and the interrupt will subsequently occur imprecisely if and when Floating-point Enabled Exception type Program interrupts are enabled by setting either or both of MSR\_\text{FE}_0,\text{FE}_1, and will also cause ESR\_\text{PIE} to be set to 1. See Section 7.6.8. Also, exception status on the exact cause is available in the Floating-Point Status and Control Register (see Section 4.2.2 and Section 4.4 of Book I).

   The precision of the Auxiliary Processor Enabled Exception type Program interrupt is implementation-dependent.

7. Auxiliary Processor exception status is commonly provided as part of the implementation.

8. Cache locking and cache locking exceptions are implementation-dependent.

9. Software must examine the instruction and the subject TLB entry to determine the exact cause of the interrupt.

10. If the Embedded.Enhanced Debug category is enabled, this interrupt is not a critical interrupt. DSRR0 and DSRR1 are used instead of CSRR0 and CSRR1.

7.6.1 Interrupt Fixed Offsets [Category: Embedded.Phased-In]

Figure 62 on page 1152 shows the 12-bit low-order effective address offset for each interrupt type. This value is the offset from the base address provided by either the IVPR (see Section 7.2.11) or the GIVPR (see Section 7.2.12).
7.6.2 Critical Input Interrupt

A Critical Input interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Critical Input exception is presented to the interrupt mechanism, and MSR_CE=1. If Category: Embedded.Hypervisor is supported, Critical Input interrupts with the exception of Guest Processor Doorbell Critical are enabled regardless of the state of MSR_CE when MSR_QS=1. While the specific definition of a Critical Input exception is implementation-dependent, it would typically be caused by the activation of an asynchronous signal that is part of the system. Also, implementations may provide an alternative means (in addition to MSR_CE) for masking the Critical Input interrupt.

CSRR0, CSRR1, and MSR are updated as follows:

CSRR0, CSRR1, and MSR are updated as follows:

**CSRR0**
- Set to the effective address of the next instruction to be executed.

**CSRR1**
- Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM** set to EPCR_ICM.
- **ME** Unchanged.
- **DE** Unchanged if category E.ED is supported; otherwise set to 0

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Hypervisor] are supported, instruction execution resumes at address IVPR_0:51 || 0x020. Otherwise, instruction execution resumes at address IVPR_0:47 || IVOR_48:59 || 0b0000.

**Programming Note**
Software is responsible for taking any action(s) that are required by the implementation in order to clear any Critical Input exception status prior to re-enabling MSR_CE in order to avoid another, redundant Critical Input interrupt.

7.6.3 Machine Check Interrupt

A Machine Check interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Machine Check exception is presented to the interrupt mechanism, and MSR_ME=1. If Category: Embedded.Hypervisor is supported, Machine Check interrupts with the exception of Guest Processor Doorbell Machine Check are enabled regardless of the state of MSR_ME when MSR_QS=1. The specific cause or causes of Machine Check exceptions are implementation-dependent, as are the details of the actions taken on a Machine Check interrupt.
If the Machine Check Extension is implemented, MCSRR0, MCSRR1, and MCSR are set, otherwise CSRR0, CSRR1, and ESR are set. The registers are updated as follows:

**CSRR0/MCSRR0**
Set to an instruction address. As closely as possible, set to the effective address of an instruction that was executing or about to be executed when the Machine Check exception occurred.

**CSRR1/MCSRR1**
Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM** \(\text{MSR}_{\text{CM}}\) is set to \(\text{EPCR}_{\text{CM}}\).
- All other defined MSR bits set to 0.

**ESR/MCSR**
Implementation-dependent.

Instruction execution resumes at address \(\text{IVPR}_{0:47} \| \text{IVOR}_{148:59} \| 0b0000\).

If the Embedded.Hypervisor category is supported, a Machine Check interrupt caused by an error in the storage subsystem, the storage subsystem may return incorrect data, that may be placed into registers and/or on-chip caches.

### 7.6.4 Data Storage Interrupt

A Data Storage interrupt may occur when no higher priority exception exists (see Section 7.9 on page 1190) and a Data Storage exception is presented to the interrupt mechanism. A Data Storage exception is caused when any of the following exceptions arises during execution of an instruction:

#### Read Access Control exception

A Read Access Control exception is caused when one of the following conditions exist.

- While in user mode (MSR\(\text{PR}=1\)), a Load or ‘load-class’ Cache Management instruction attempts to access a location in storage that is not user mode read enabled (i.e. page access control bit \(\text{UR}=0\)).
- While in supervisor mode (MSR\(\text{PR}=0\)), a Load or ‘load-class’ Cache Management instruction attempts to access a location in storage that is not supervisor mode read enabled (i.e. page access control bit \(\text{SR}=0\)).

#### Write Access Control exception

A Write Access Control exception is caused when one of the following conditions exist.

- While in user mode (MSR\(\text{PR}=1\)), a Store or ‘store-class’ Cache Management instruction attempts to access a location in storage that is not user mode write enabled (i.e. page access control bit \(\text{UW}=0\)).
- While in supervisor mode (MSR\(\text{PR}=0\)), a Store or ‘store-class’ Cache Management instruction attempts to access a location in storage that is not
supervisor mode write enabled (i.e. page access control bit SW=0).

**Byte Ordering exception**

A Byte Ordering exception may occur when the implementation cannot perform the data storage access in the byte order specified by the Endian storage attribute of the page being accessed.

**Cache Locking exception**

A Cache Locking exception may occur when the locked state of one or more cache lines has the potential to be altered. This exception is implementation-dependent.

**Storage Synchronization exception**

A Storage Synchronization exception will occur when an attempt is made to execute a Load and Reserve or Store Conditional instruction from or to a location that is Write Through Required or Caching Inhibited (if the interrupt does not occur then the instruction executes correctly: see Section 4.4.2 of Book II).

If a stbcx, sthcx, stwcx, stdcx, or stqcx, would not perform its store in the absence of a Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional Store to the specified effective address would cause a Data Storage interrupt, it is implementation-dependent whether a Data Storage interrupt occurs.

**Page Table Fault exception**

A Page Table Fault exception is caused when a Page Table translation occurs for a data access due to a Load, Store or Cache Management instruction and the Page Table Entry that is accessed is invalid (PTE Valid bit = 0).

**TLB Ineligible exception**

A TLB Ineligible exception is caused when a Page Table translation occurs for a data access due to a Load, Store or Cache Management instruction and any of the following conditions are true:

- The only TLB entries that can be used to hold the translation for the virtual address have IPROT=1
- No TLB array can be loaded from the Page Table for the page size specified by the PTE.
- The PTE_ARPN is treated as an LPN (The Embedded.Hypervisor category is supported) and there is no TLB array that meets all the following conditions.
- The TLB array supports the page size specified by the PTE.
- The TLB array can be loaded from the Page Table (TLBnCFGPT = 1).

If the Embedded.Hypervisor category is supported, an Data Storage interrupt resulting from a TLB Ineligible exception is always directed to hypervisor state regardless of the setting of EPCR_DSIGS.

**Virtualization Fault exception [Category: Embedded.Hypervisor]**

A Virtualization Fault exception will occur when a Load, Store, or Cache Management Instruction attempts to access a location in storage that has the Virtualization Fault (VF) bit set. A Data Storage interrupt resulting from a Virtualization Fault exception is always directed to hypervisor state regardless of the setting of EPCR_DSIGS.

Instructions lswx or stswx with a length of zero, icbt, dcbt, dcbtep, dcbtst, dcbtstep, or dcba cannot cause a Data Storage interrupt, regardless of the effective address.

**Programming Note**

The icbi, icbiep, icbt, icbtls and icbwc instructions are treated as Loads from the addressed byte with respect to address translation and protection. These Instruction Cache Management instructions use MSR_DS, not MSR_IS, to determine translation for their operands. Instruction Storage exceptions and Instruction TLB Miss exceptions are associated with the ‘fetching’ of instructions not with the ‘execution’ of instructions. Data Storage exceptions and Data TLB Miss exceptions are associated with the ‘execution’ of Instruction Cache Management instructions. One exception to the above is that icbtls and icbwc only cause a Data Storage exception if they have neither execute access nor read access.

When a Data Storage interrupt occurs, the thread suppresses the execution of the instruction causing the Data Storage exception.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, MSR, DEAR, and ESR are updated as follows:

<table>
<thead>
<tr>
<th>MSR</th>
<th>Set to the contents of the MSR at the time of the interrupt.</th>
</tr>
</thead>
<tbody>
<tr>
<td>CM</td>
<td>MSR_CM is set to EPCR_ICM.</td>
</tr>
<tr>
<td>DE</td>
<td>Unchanged.</td>
</tr>
</tbody>
</table>

All other defined MSR bits set to 0.

| DEAR | Set to the effective address of a byte that is both within the range of the bytes being accessed by the Storage Access or Cache Management instruction, and within the |

---

Chapter 7. Interrupts and Exceptions 1167
page whose access caused the Data Storage exception.

ESR

FP Set to 1 if the instruction causing the interrupt is a floating-point load or store; otherwise set to 0.

ST Set to 1 if the instruction causing the interrupt is a Store or ‘store-class’ Cache Management instruction; otherwise set to 0.

DLK0:1 Set to an implementation-dependent value due to a Cache Locking exception causing the interrupt.

AP Set to 1 if the instruction causing the interrupt is an Auxiliary Processor load or store; otherwise set to 0.

BO Set to 1 if the instruction caused a Byte Ordering exception; otherwise set to 0.

TLBI Set to 1 if a TLB Ineligible exception occurred during a Page Table translation for the instruction causing the interrupt; otherwise set to 0.

PT If a Page Table Fault or Read or Write Access Control exception occurred during a Page Table translation for the instruction causing the interrupt, then PT is set to 1 if no TLB entry was created from the Page Table and is set to an implementation-dependent value if a TLB entry was created. See Section 6.7.4 for rules about TLB updates. If no Page Table Fault or Read or Write Access Control exception occurred during a Page Table translation for the instruction causing the interrupt, set to 0.

SPV Set to 1 if the instruction causing the interrupt is a SPE operation or a Vector operation; otherwise set to 0.

VLEMI Set to 1 if the instruction causing the interrupt resides in VLE storage.

EPID Set to 1 if the instruction causing the interrupt is an External Process ID instruction; otherwise set to 0.

All other defined ESR bits are set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to guest supervisor state GSRR0, GSRR1, GDEAR, and GESR are set in place of SRR0, SRR1, DEAR, and ESR, respectively. The MSR is set as follows:

MSR

CM MSR_CM is set to EPCR_GICM.

CE, ME, GS, DE Unchanged.

Bits in the MSR corresponding to set bits in the MSRP register are left unchanged.

All other defined MSR bits set to 0.

The following is a prioritized listing of the various exceptions which cause a Data Storage interrupt and the corresponding ESR bit, if applicable. Even though multiple of these exceptions may occur, at most one of the following exceptions is reported in the ESR.

1. Cache Locking <E.CL>: DLK0:1
2. Page Table Fault <E.PT>: PT
3. Virtualization Fault <E.HV>
4. TLB Ineligible <E.PT>: TLBI
5. Byte Ordering: BO
6. Read Access or Write Access: If the exception occurred during a Page Table translation, PT <E.PT>

Programming Note

Since some Data Storage exceptions are not mutually exclusive, system software may need to examine the TLB entry or the Page Table entry accessed by the data storage access in order to determine whether additional exceptions may have also occurred.

If Category Embedded.Hypervisor is supported and the interrupt is directed to the guest state, instruction execution resumes at the address given by one of the following:

- GIVPR0:47 || GIVOR248:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- GIVPR0:51||0x060 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

Otherwise, instruction execution resumes at the address given by one of the following:

- IVPR0:47 || IVOR248:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVPR0:51||0x060 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

7.6.5 Instruction Storage Interrupt

An Instruction Storage interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and an Instruction Storage exception is presented to the interrupt mechanism. An Instruction Storage exception is caused when any of the following exceptions arises during execution of an instruction:

Execute Access Control exception

An Execute Access Control exception is caused when one of the following conditions exist.

- While in user mode (MSR_PR=1), an instruction fetch attempts to access a location in storage that is not user mode execute enabled (i.e. page access control bit UX=0).
- While in supervisor mode (MSR_PR=0), an instruction fetch attempts to access a location in storage
that is not supervisor mode execute enabled (i.e. page access control bit SX=0).

**Byte Ordering exception**

A Byte Ordering exception may occur when the implementation cannot perform the instruction fetch in the byte order specified by the Endian storage attribute of the page being accessed.

**Page Table Fault exception**

A Page Table Fault exception is caused when a Page Table translation occurs for an instruction fetch and the Page Table Entry that is accessed is invalid (Valid bit = 0).

**TLB Ineligible exception**

A TLB Ineligible exception is caused when a Page Table translation occurs for an instruction fetch and any of the following conditions are true.

- The only TLB entries that can be used to hold the translation for the virtual address have IPROT=1
- No TLB array can be loaded from the Page Table for the page size specified by the PTE.
- The PTEARPN is treated as an LPN (The Embedded.Hypervisor category is supported) and there is no TLB array that meets all the following conditions.
  - The TLB array supports the page size specified by the PTE.
  - The TLB array can be loaded from the Page Table (TLBnCFGPT = 1).

If the Embedded.Hypervisor category is supported, an Instruction Storage interrupt resulting from a TLB Ineligible exception is always directed to hypervisor state regardless of the setting of EPCRISIGS.

When an Instruction Storage interrupt occurs, the thread suppresses the execution of the instruction causing the Instruction Storage exception.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, MSR, and ESR are updated as follows:

**SRR0**

Set to the effective address of the instruction causing the Instruction Storage interrupt.

**SRR1**

Set to the contents of the MSR at the time of the interrupt.

**MSR**

- **CM**
  - MSR<sub>CM</sub> is set to EPCR<sub>ICM</sub>
  - CE, ME, DE
  - Unchanged.

- All other defined MSR bits set to 0.

**ESR**

- **BO**
  - Set to 1 if the instruction fetch caused a Byte Ordering exception; otherwise set to 0.

- **TLBI**
  - Set to 1 if a TLB Ineligible exception occurred during a Page Table translation for the instruction causing the interrupt; otherwise set to 0.

- **PT**
  - If a Page Table Fault or an Execute Access Control exception occurred during a Page Table translation for the instruction causing the interrupt, then PT is set to 1 if no TLB entry was created from the Page Table and is set to an implementation-dependent value if a TLB entry was created. See Section 6.7.4 for rules about TLB updates. If no Page Table Fault or Execute Access Control exception occurred during a Page Table translation for the instruction causing the interrupt, set to 0.

- **VLEMI**
  - Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined ESR bits are set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to guest supervisor state, GSRR0, GSRR1, and GESR are set in place of SRR0, SRR1, and ESR, respectively. The MSR is set as follows:

**MSR**

- **CM**
  - MSR<sub>CM</sub> is set to EPCR<sub>GICM</sub>
- CE, ME, GS, DE
  - Unchanged.

- Bits in the MSR corresponding to set bits in the MSRP register are left unchanged.

All other defined MSR bits set to 0.

The following is a prioritized listing of the various exceptions which cause a Instruction Storage interrupt and the corresponding ESR bit, if applicable. Even though multiple of these exceptions may occur, at most one of the following exceptions is reported in the ESR.

1. Page Table Fault <E.PT>: PT
2. TLB Ineligible <E.PT>: TLBI
3. Byte Ordering exception: BO
4. Execute Access: If the exception occurred during a Page Table translation, PT <E.PT>

---

**Programming Note**

Since some Instruction Storage exceptions are not mutually exclusive, system software may need to examine the TLB entry or the Page Table entry accessed by the data storage access in order to determine whether additional exceptions may have also occurred.
If Category Embedded.Hypervisor is supported and the interrupt is directed to the guest state, instruction execution resumes at the address given by one of the following.
- GIVPR0:47 || GIVOR348:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- GIVPR0:51||0x080 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

Otherwise, instruction execution resumes at the address given by one of the following.
- IVPR0:47 || IVOR348:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVPR0:51||0x080 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

### 7.6.6 External Input Interrupt

An External Input interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), an External Input exception is presented to the interrupt mechanism, and the interrupt is enabled. While the specific definition of an External Input exception is implementation-dependent, it would typically be caused by the activation of an asynchronous signal that is part of the processing system. Also, implementations may provide an alternative means (in addition to the enabled criteria) for masking the External Input interrupt.

If Category: Embedded.Hypervisor is supported, External Input interrupts are enabled if:

(EPCR<sub>EXTGS</sub> = 0) & ((MSR<sub>GS</sub> =1) | (MSR<sub>EE</sub>=1))

or

(EPCR<sub>EXTGS</sub> = 1) & (MSR<sub>GS</sub> =1) & (MSR<sub>EE</sub>=1)

Otherwise, External Input interrupts are enabled if MSR<sub>EE</sub>=1.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, and MSR are updated as follows:

**SRR0** Set to the effective address of the next instruction to be executed.

**SRR1** Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM** MSR<sub>CM</sub> is set to EHSR<sub>ICM</sub>.
- **CE** Unchanged.
- **ME** Unchanged.
- **GS** Unchanged.
- **DE** Unchanged.

All other defined MSR bits set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to the guest supervisor state, GSRR0 and GSRR1 are set in place of SRR0 and SRR1, respectively. The MSR is set as follows:

**MSR**
- **CM** MSR<sub>CM</sub> is set to EPCR<sub>GICM</sub>.
- **CE** ME,GS,DE Unchanged.

Bits in the MSR corresponding to set bits in the MSR register are left unchanged.

All other defined MSR bits set to 0.

If Category Embedded.Hypervisor is supported and the interrupt is directed to the guest state, instruction execution resumes at the address given by one of the following.
- GIVPR0:47 || GIVOR448:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- GIVPR0:51||0x0A0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

Otherwise, instruction execution resumes at the address given by one of the following.
- IVPR0:47 || IVOR448:59||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVPR0:51||0x0A0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

---

**Programming Note**

Software is responsible for taking whatever action(s) are required by the implementation in order to clear any External Input exception status prior to re-enabling MSR<sub>EE</sub> in order to avoid another, redundant External Input interrupt.

### 7.6.7 Alignment Interrupt

An Alignment interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and an Alignment exception is presented to the interrupt mechanism. An Alignment exception may be caused when the implementation cannot perform a data storage access for one of the following reasons:

- The operand of a single-register Load or Store is not aligned.
- The instruction is a Load Multiple or Store Multiple, or a Move Assist for which the length of the storage operand is not zero.
- The operand of dcbz or dcbzep is in storage that is Write Through Required or Caching Inhibited, or one of these instructions is executed in an implementation that has either no data cache or a Write Through data cache or the line addressed by the instruction cannot be established in the cache because the cache is disabled or locked.
- The operand of a Store, except Store Conditional, or Store String for which the length of the storage operand is zero, is in storage that is Write-Through Required.

For **lmw** and **stmw** with an operand that is not word-aligned, and for **Load and Reserve** and **Store**
Conditional instructions with an operand that is not aligned, an implementation may yield boundedly undefined results instead of causing an Alignment interrupt. A Store Conditional to Write Through Required storage may either cause a Data Storage interrupt, cause an Alignment interrupt, or correctly execute the instruction. For all other cases listed above, an implementation may execute the instruction correctly instead of causing an Alignment interrupt. (For dcbz or dcbzep, 'correct' execution means setting each byte of the block in main storage to 0x00.)

When an Alignment interrupt occurs, the thread suppresses the execution of the instruction causing the Alignment exception.

**Programming Note**

The architecture does not support the use of an unaligned effective address by Load and Reserve and Store Conditional instructions. If an Alignment interrupt occurs because one of these instructions specifies an unaligned effective address, the Alignment interrupt handler must not attempt to emulate the instruction, but instead should treat the instruction as a programming error.

When an Alignment interrupt occurs, the thread suppresses the execution of the instruction causing the Alignment exception.

**SRR0, SRR1, MSR, DEAR, and ESR are updated as follows:**

**SRR0**
Set to the effective address of the instruction causing the Alignment interrupt.

**SRR1**
Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM**
  MSR_{CM} is set to EPCR_{ICM}.
- **CE, ME, DE**
  Unchanged
- **CE, ME, DE, ICM**
  Unchanged.

All other defined MSR bits set to 0.

**DEAR**
Set to the effective address of a byte that is both within the range of the bytes being accessed by the Storage Access or Cache Management instruction, and within the page whose access caused the Alignment exception.

**ESR**
- **FP**
  Set to 1 if the instruction causing the interrupt is a floating-point load or store; otherwise set to 0.
- **ST**
  Set to 1 if the instruction causing the interrupt is a Store; otherwise set to 0.
- **AP**
  Set to 1 if the instruction causing the interrupt is an Auxiliary Processor load or store; otherwise set to 0.

**SPV**
Set to 1 if the instruction causing the interrupt is a SPE operation or a Vector operation; otherwise set to 0.

**VLEMI**
Set to 1 if the instruction causing the interrupt resides in VLE storage.

**EPID**
Set to 1 if the instruction causing the interrupt is an External Process ID instruction; otherwise set to 0.

All other defined ESR bits are set to 0.

If Interrupt Fixed Offsets [Category: Embedded, Phased-In] are supported, instruction execution resumes at address IVPR_{0:51} || 0x0C0. Otherwise, instruction execution resumes at address IVPR_{0:47} || IVORS_{54:59} || 0b0000.

### 7.6.8 Program Interrupt

A Program interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Program exception is presented to the interrupt mechanism, and, for Floating-point Enabled exception, MSR_{FE0, FE1} are non-zero. A Program exception is caused when any of the following exceptions arises during execution of an instruction:

#### Floating-point Enabled exception

A Floating-point Enabled exception is caused when FPSCR_{FEX} is set to 1 by the execution of a floating-point instruction that causes an enabled exception, including the case of a Move To FPSCR instruction that causes an exception bit and the corresponding enable bit both to be 1. Note that in this context, the term ‘enabled exception’ refers to the enabling provided by control bits in the Floating-Point Status and Control Register. See Section 4.2.2 of Book I.

#### Auxiliary Processor Enabled exception

The cause of an Auxiliary Processor Enabled exception is implementation-dependent.

#### Illegal Instruction exception

An Illegal Instruction exception does occur when execution is attempted of any of the following kinds of instructions.

- a reserved-illegal instruction
- when MSR_{PR}=1 (user mode), an mtspr or mfspr that specifies an spr value with sprs<sub>s</sub>=0 (user-mode accessible) that represents an unimplemented Special Purpose Register

An Illegal Instruction exception may occur when execution is attempted of any of the following kinds of instructions. If the exception does not occur, the alternative is shown in parentheses.

- an instruction that is in invalid form (boundedly undefined results)
an *lswx* instruction for which register RA or register RB is in the range of registers to be loaded (boundedly undefined results)

- a defined instruction that is not implemented by the implementation (*Unimplemented Operation exception*)

**Privileged Instruction exception**

A Privileged Instruction exception occurs when MSRPR=1 and execution is attempted of any of the following kinds of instructions.

- a privileged instruction
- an *mtspr* or *mfspr* instruction that specifies an spr value with spr6=1

**Trap exception**

A Trap exception occurs when any of the conditions specified in a *Trap* instruction are met and the exception is not also enabled as a Debug interrupt. If enabled as a Debug interrupt (i.e. DBCR0TRAP=1, DBCR0IDM=1, and MSR DE=1), then a Debug interrupt will be taken instead of the Program interrupt.

**Unimplemented Operation exception**

An Unimplemented Operation exception may occur when execution is attempted of a defined instruction that is not implemented by the implementation. Otherwise an Illegal Instruction exception occurs.

An Unimplemented Operation exception may also occur when the thread is in 32-bit mode and execution is attempted of an instruction that is part of the 64-Bit category. Otherwise the instruction executes normally.

**SRR0, SRR1, MSR, and ESR are updated as follows:**

- **SRR0**
  - For all Program interrupts except an Enabled exception when in one of the imprecise modes (see Section 4.2.1 on page 1035) or when a disabled exception is subsequently enabled, set to the effective address of the instruction that caused the Program interrupt.
  - For an imprecise Enabled exception, set to the effective address of the excepting instruction or to the effective address of some subsequent instruction. If it points to a subsequent instruction, that instruction has not been executed, and ESRPIE is set to 1. If a subsequent instruction is an *sync* or *isync*, SRR0 will point at the *sync* or *isync* instruction, or at the following instruction.
  - If FPSCR FEX=1 but both MSRFE0=0 and MSRFE1=0, an Enabled exception type Program interrupt will occur imprecisely prior to or at the next synchronizing event if these MSR bits are altered by any instruction that can set the MSR so that the expression
    \[(\text{MSRFE0} \lor \text{MSRFE1}) \& \text{FPSCR}_{\text{FEX}}\]
    is 1. When this occurs, SRR0 is loaded with the address of the instruction that would have executed next, not with the address of the instruction that modified the MSR causing the interrupt, and ESRPIE is set to 1.

- **SRR1**
  - Set to the contents of the MSR at the time of the interrupt.

- **MSR**
  - **CM**
    - MSR_{CM} is set to EPCR_{ICM}.
  - **CE, ME, DE**
    - Unchanged
  - **All other defined MSR bits** set to 0.

- **ESR**
  - **PIL**
    - Set to 1 if an Illegal Instruction exception type Program interrupt; otherwise set to 0
  - **PPR**
    - Set to 1 if a Privileged Instruction exception type Program interrupt; otherwise set to 0
  - **PTR**
    - Set to 1 if a Trap exception type Program interrupt; otherwise set to 0
  - **PUO**
    - Set to 1 if an Unimplemented Operation exception type Program interrupt; otherwise set to 0
  - **FP**
    - Set to 1 if the instruction causing the interrupt is a floating-point instruction; otherwise set to 0.
  - **PIE**
    - Set to 1 if a Floating-point Enabled exception type Program interrupt, and the address saved in SRR0 is not the address of the instruction causing the exception (i.e. the instruction that caused FPSCR_{FEX} to be set); otherwise set to 0.
  - **AP**
    - Set to 1 if the instruction causing the interrupt is an Auxiliary Processor instruction; otherwise set to 0.
  - **SPV**
    - Set to 1 if the instruction causing the interrupt is a SPE operation or a Vector operation; otherwise set to 0.
  - **VLEMI**
    - Set to 1 if the instruction causing the interrupt resides in VLE storage.
  - **All other defined ESR bits** set to 0.
  - If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR_{0:51} || 0x0E0. Otherwise, instruction execution resumes at address IVPR_{0:47} || IVOR6_{48:59} || 0b0000.

**7.6.9 Floating-Point Unavailable Interrupt**

A Floating-Point Unavailable interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), an attempt is made to execute a floating-point instruction (i.e. any instruction listed in Section 4.6 of Book I), and MSRFP=0.
When a Floating-Point Unavailable interrupt occurs, the hardware suppresses the execution of the instruction causing the Floating-Point Unavailable interrupt.

SRR0, SRR1, and MSR are updated as follows:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.
- **MSR**
  - **CM**: MSR_CM is set to EPCR_ICM.
  - **VLEMI**: Set to 1 if the instruction causing the interrupt resides in VLE storage.
  - **CE, ME, DE**: Unchanged.
  - All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x100. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR748:59|| 0b0000.

### 7.6.10 System Call Interrupt

A System Call interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and a **System Call** (sc) instruction is executed.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, and MSR are updated as follows:

- **SRR0**: Set to the effective address of the instruction after the **sc** instruction.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.

- **MSR**
  - **CM**: MSR_CM is set to EPCR_ICM.
  - **VLEMI**: Set to 1 if the instruction causing the interrupt resides in VLE storage.
  - **CE, ME, DE**: Unchanged.
  - All other defined MSR bits set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to guest supervisor state, MSR0G and GSR0 are set in place of SRR0 and SRR1, respectively. The MSR is set as follows:

- **MSR**
  - **CM**: MSR_CM is set to EPCR_GICM.
  - **CE, ME, GS, DE**: Unchanged.
  - All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x140. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR748:59|| 0b0000.

### 7.6.11 Auxiliary Processor Unavailable Interrupt

An Auxiliary Processor Unavailable interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), an attempt is made to execute an Auxiliary Processor instruction (including Auxiliary Processor loads, stores, and moves), the target Auxiliary Processor is present on the implementation, and the Auxiliary Processor is configured as unavailable. Details of the Auxiliary Processor, its instruction set, and its configuration are implementation-dependent. See User’s Manual for the implementation.

When an Auxiliary Processor Unavailable interrupt occurs, the hardware suppresses the execution of the instruction causing the Auxiliary Processor Unavailable interrupt.

Registers SRR0, SRR1, and MSR are updated as follows:

- **SRR0**: Set to the effective address of the instruction that caused the interrupt.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.

- **MSR**
  - **CM**: MSR_CM is set to EPCR_ICM.
  - **CE, ME, DE**: Unchanged.
  - All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:31 || 0x140. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR748:59|| 0b0000.

### 7.6.12 Decrementer Interrupt

A Decrementer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Decrementer exception exists (TSR_DIS=1), and the excep-
tion is enabled. If Category: Embedded.Hypervisor is supported, the interrupt is enabled by TCR[DIE]=1 and (MSR[EE]=1 or MSR[GS]=1). Otherwise, the interrupt is enabled by TCR[DIE]=1 and MSR[EE]=1. See Section 9.3 on page 1199.

**Programming Note**

MSR[EE] also enables the External Input and Fixed-Interval Timer interrupts.

SRR0, SRR1, MSR, and TSR are updated as follows:

- **SRR0**: Set to the effective address of the next instruction to be executed.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.
- **MSR**: 
  - **CM**: MSR[CM] is set to EPCR[CM].
  - **CE, ME, DE**: Unchanged
  - All other defined MSR bits set to 0.
- **TSR** (See Section 9.7.1 on page 1204.):
  - **DIS**: Set to 1.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address GIVPR[0:51] || 0x160. Otherwise, instruction execution resumes at address GIVPR[0:47] || GIVOR[10:59] || 0b0000.

**7.6.13 Guest Decrementer Interrupt**

A Guest Decrementer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Guest Decrementer exception exists (GTSR[DIS]=1), and the exception is enabled. The interrupt is enabled by GTCR[DIE]=1 and MSR[EE]=1 and MSR[GS]=1. See Section 9.7 on page 1203.

**Programming Note**

Software is responsible for clearing the Decrementer exception status prior to re-enabling the MSR[EE] bit in order to avoid another redundant Decrementer interrupt. To clear the Decrementer exception, the interrupt handling routine must clear TSR[DIS]. Clearing is done by writing a word to TSR using `mtspr` with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the TSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

Hypervisor software can modify the value of the GTSR by writing the desired value to the GTSRWR. Bits specified in the GTSRWR directly set or clear the corresponding implemented bits in the GTSR.

**7.6.14 Fixed-Interval Timer Interrupt**

A Fixed-Interval Timer interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Fixed-Interval Timer exception exists (TSR[FIS]=1), and the exception is enabled. If Category: Embedded.Hypervisor is supported, the interrupt is enabled by TCR[FIE]=1 and (MSR[EE]=1 or MSR[GS]=1). Otherwise, the interrupt is enabled by TCR[FIE]=1 and MSR[EE]=1. See Section 9.9 on page 1208.
SRR0, SRR1, MSR, and TSR are updated as follows:

**SRR0**
Set to the effective address of the next instruction to be executed.

**SRR1**
Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM**: MSR\textsubscript{CM} is set to EPCR\textsubscript{ICM}.
- CE, ME, DE
  - Unchanged.
- All other defined MSR bits set to 0.

**TSR**
(See Section 9.7.1 on page 1204.)
- **FIS**: Set to 1.

If Interrupt Fixed Offsets [Category: Embedded, Phased-In] are supported, instruction execution resumes at address IVPR\textsubscript{0:51} || 0x180. Otherwise, instruction execution resumes at address IVPR\textsubscript{0:47} || IVOR\textsubscript{1148:59} || 0b0000.

---

**Programming Note**
Software is responsible for clearing the Fixed-Interval Timer exception status prior to re-enabling the MSR\textsubscript{EE} bit in order to avoid another redundant Fixed-Interval Timer interrupt. To clear the Fixed-Interval Timer exception, the interrupt handling routine must clear TSR\textsubscript{FIS}. Clearing is done by writing a word to TSR using \texttt{mtspr} with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the TSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

Hypervisor software can modify the value of the GTSR by writing the desired value to the GTSRWR. Bits specified in the GTSRWR directly set or clear the corresponding implemented bits in the GTSR.

---

### 7.6.15 Guest Fixed Interval Timer Interrupt

A Guest Decrementer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Guest Decrementer exception exists (GTSR\textsubscript{DIS}=1), and the exception is enabled. The interrupt is enabled by TCR[DIE]=1 and MSR\textsubscript{EE}=1 and MSR\textsubscript{GS}=1. See Section 9.8 on page 1206.

**Programming Note**
MSR\textsubscript{EE} also enables the External Input and Guest Fixed-Interval Timer interrupts.

**GSRR0, GSRR1, MSR, and GTSR** are updated as follows:

**GSRR0**
Set to the effective address of the next instruction to be executed.

---

**Programming Note**
MSR\textsubscript{CE} also enables the Critical Input interrupt.

**GSRR0, GSRR1, MSR, and GTSR** are updated as follows:

**GSRR0**
Set to the effective address of the next instruction to be executed.
CM  MSR_CM is set to EPCR_ICM.
ME  Unchanged.
DE  Unchanged if category E.ED is supported; otherwise set to 0.

All other defined MSR bits set to 0.

TSR  (See Section 9.7.1 on page 1204.)
WIS  Set to 1.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR_0:51 || 0x1A0. Otherwise, instruction execution resumes at address IVPR_0:47 || IVOR_1248:59 || 0b0000.

7.6.17 Guest Watchdog Timer

Interrupt

A Guest Watchdog Timer interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Guest Watchdog Timer exception exists (GTSR_WIS=1), and the exception is enabled. The interrupt is enabled by GTCR_WIE=1 and MSR_CE = 1 and MSR_GS=1. See Section 9.8 on page 1206.

--- Programming Note

Software is responsible for clearing the Watchdog Timer exception status prior to re-enabling the MSR_CE bit in order to avoid another redundant Watchdog Timer interrupt. To clear the Watchdog Timer exception, the interrupt handling routine must clear TSR_WIS. Clearing is done by writing a word to TSR using mtspwr with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the TSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect. Hypervisor software can modify the value of the GTSR by writing the desired value to the GTSRWR. Bits specified in the GTSRWR directly set or clear the corresponding implemented bits in the GTSR.

--- Programming Note

As all Watchdog Timer interrupts are directed to the hypervisor, it is the responsibility of hypervisor software to reflect interrupts generated by the Guest Watchdog Timer to the guest supervisor.

7.6.18 Data TLB Error Interrupt

A Data TLB Error interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and any of the following Data TLB Error exceptions is presented to the interrupt mechanism.

TLB Miss exception

Caused when the virtual address associated with a data storage access does not match any valid entry in the TLB as specified in Section 6.7.2 on page 1081.

If a stbcx, sthcx, stwcx, stdcx, or stqcx would not perform its store in the absence of a Data Storage interrupt, and a non-conditional Store to the specified effective address would cause a Data Storage interrupt, it is implementation dependent whether a Data Storage interrupt occurs.

When a Data TLB Error interrupt occurs, the hardware suppresses the execution of the instruction causing the Data TLB Error interrupt.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, MSR, DEAR, and ESR are updated as follows:

SRR0  Set to the effective address of the instruction causing the Data TLB Error interrupt.

Software is responsible for clearing the Guest Watchdog Timer exception status prior to re-enabling the MSR_CE bit in order to avoid another redundant Guest Watchdog Timer interrupt. To clear the Guest Watchdog Timer exception, the interrupt handling routine must clear TSR_WIS. Clearing is done by writing a word to TSR using mtspwr with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the TSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

Programming Note

Software is responsible for clearing the Guest Watchdog Timer exception status prior to re-enabling the MSR_CE bit in order to avoid another redundant Guest Watchdog Timer interrupt. To clear the Guest Watchdog Timer exception, the interrupt handling routine must clear TSR_WIS. Clearing is done by writing a word to TSR using mtspwr with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the TSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.
SRR1 Set to the contents of the MSR at the time of the interrupt.

MSR CM MSR_CM is set to EHSRICM.

CE, ME, DE Unchanged.

All other defined MSR bits set to 0.

DEAR Set to the effective address of a byte that is both within the range of the bytes being accessed by the Storage Access or Cache Management instruction, and within the page whose access caused the Data TLB Error exception.

ESR ST Set to 1 if the instruction causing the interrupt is a Store, dcbi, dcbz, or dcbzep instruction; otherwise set to 0.

FP Set to 1 if the instruction causing the interrupt is a floating-point load or store; otherwise set to 0.

AP Set to 1 if the instruction causing the interrupt is an Auxiliary Processor load or store; otherwise set to 0.

SPV Set to 1 if the instruction causing the interrupt is a SPE operation or a Vector operation; otherwise set to 0.

VLEMI Set to 1 if the instruction causing the interrupt resides in VLE storage.

EPID Set to 1 if the instruction causing the interrupt is an External Process ID instruction; otherwise set to 0.

All other defined ESR bits are set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to guest supervisor state, GSRR0, GSRR1, GDEAR, and GESR are set in place of SRR0, SRR1, DEAR, and ESR, respectively. The MSR is set as follows:

MSR CM MSR_CM is set to EPCRGICM.

CE, ME, GS, DE Unchanged.

All other defined MSR bits set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to the guest state, instruction execution resumes at the address given by one of the following:
- IVPR_{0:47} || IVOR13_{48:59}||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- IVPR_{0:51}||0x1C0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

7.6.19 Instruction TLB Error Interrupt

An Instruction TLB Error interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and any of the following Instruction TLB Error exceptions is presented to the interrupt mechanism.

**TLB Miss exception**

Caused when the virtual address associated with an instruction fetch does not match any valid entry in the TLB as specified in Section 6.7.2 on page 1081.

When an Instruction TLB Error interrupt occurs, the hardware suppresses the execution of the instruction causing the Instruction TLB Miss exception.

If Category: Embedded.Hypervisor is not supported or if Category: Embedded.Hypervisor is supported and the interrupt is directed to hypervisor state, SRR0, SRR1, and MSR are updated as follows:

SRR0 Set to the effective address of the instruction causing the Instruction TLB Error interrupt.

SRR1 Set to the contents of the MSR at the time of the interrupt.

MSR CM MSR_CM is set to EPCRICM.

CE, ME, GS, DE Unchanged.

All other defined MSR bits set to 0.

If Category: Embedded.Hypervisor is supported and the interrupt is directed to the guest state, instruction execution resumes at the address given by one of the following:
- GIVPR_{0:47} || GIVOR13_{48:59}||0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.
- GIVPR_{0:51}||0x1C0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.
GIVPR\textsubscript{0,47} \parallel GIVOR14\textsubscript{48-59} \parallel 0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.

GIVPR\textsubscript{0,51} \parallel 0x1E0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

Otherwise, instruction execution resumes at the address given by one of the following.

IVPR\textsubscript{0,47} \parallel IVOR14\textsubscript{48-59} \parallel 0b0000 if IVORs [Category: Embedded.Phased-Out] are supported.

IVPR\textsubscript{0,51} \parallel 0x1E0 if Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported.

7.6.20 Debug Interrupt

A Debug interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), a Debug exception exists in the DBSR, and Debug interrupts are enabled (DBCR0\_DM=1 and MSR\_DE=1). A Debug exception occurs when a Debug Event causes a corresponding bit in the DBSR to be set. See Section 10.5.

If the Embedded.Enhanced Debug category is not supported or is supported and is not enabled, CSRR0, CSRR1, MSR, and DBSR are updated as follows. If the Embedded.Enhanced Debug category is supported and is enabled, DSRR0 and DSRR1 are updated as specified below and CSRR0 and CSRR1 are not changed. The means by which the Embedded.Enhanced Debug category is enabled is implementation-dependent.

CSRR0 or DSRR0 [Category: Embedded.Enhanced Debug]

For Debug exceptions that occur while Debug interrupts are enabled (DBCR0\_DM=1 and MSR\_DE=1), CSRR0 is set as follows:

- For Instruction Address Compare (IAC1, IAC2, IAC3, IAC4), Data Address Compare (DAC1R, DAC1W, DAC2R, DAC2W), Trap (TRAP), or Branch Taken (BRT) debug exceptions, set to the address of the instruction causing the Debug interrupt.
- For Instruction Complete (ICMP) debug exceptions, set to the address of the instruction that would have executed after the one that caused the Debug interrupt.
- For Unconditional Debug Event (UDE) debug exceptions, set to the address of the instruction that would have executed next if the Debug interrupt had not occurred.
- For Interrupt Taken (IRPT) debug exceptions, set to the interrupt vector value of the interrupt that caused the Interrupt Taken debug event.
- For Return From Interrupt (RET) debug exceptions, set to the address of the \textit{rfi} instruction that caused the Debug interrupt.
- For Critical Interrupt Taken (CRPT) debug exceptions, DSRR0 is set to the address of the first instruction of the critical interrupt handler. CSRR0 is unaffected.
- For Critical Interrupt Return (CRET) debug exceptions, DSRR0 is set to the address of the \textit{rfci} instruction that caused the Debug interrupt.

See
Section 10.4.10, “Critical Interrupt Return Debug Event [Category: Embedded.Enhanced Debug].”

For Debug exceptions that occur while Debug interrupts are disabled (DBCR0\_IDM=0 or MSR\_DE=0), a Debug interrupt will occur at the next synchronizing event if DBCR0\_IDM and MSR\_DE are modified such that they are both 1 and if the Debug exception Status is still set in the DBSR. When this occurs, CSRR0 or DSRR0 [Category:Embedded.Enhanced Debug] is set to the address of the instruction that would have executed next, not with the address of the instruction that modified the Debug Control Register 0 or MSR and thus caused the interrupt.

**CSRR1** or **DSRR1** [Category: Embedded.Enhanced Debug]
Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM** MSRCM is set to EPCR\_ICM.
- **ME** Unchanged

All other supported MSR bits set to 0.

**DBSR**
Set to indicate type of Debug Event (see Section 10.5.2)

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x040. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR15:59|| 0b0000.

### 7.6.21 SPE/Embedded Floating-Point/Vector Unavailable Interrupt

[Categories: SPE.Embedded Float Scalar Double, SPE.Embedded Float Vector, Vector]

The SPE/Embedded Floating-Point/Vector Unavailable interrupt occurs when no higher priority exception exists, and an attempt is made to execute an SPE, SPE.Embedded Float Scalar Double, SPE.Embedded Float Vector, or Vector instruction and MSR\_SPV = 0.

When an Embedded Floating-Point Unavailable interrupt occurs, the hardware suppresses the execution of the instruction causing the exception.

SRR0, SRR1, MSR, and ESR are updated as follows:

**SRR0** Set to the effective address of the instruction causing the Embedded Floating-Point Unavailable interrupt.

**SRR1** Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM** MSRCM is set to EPCR\_ICM.
- **CE, ME, DE** Unchanged

**ESR**
- **SPV** Set to 1.
- **VLEMI** Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined ESR bits are set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x200. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR32:59|| 0b0000.

**Programming Note**

This interrupt is also used by the Signal Processing Engine in the same manner. It should be used by software to determine if the application is using the upper 32 bits of the GPRs in a 32-bit implementation and thus be required to save and restore them on context switch.
7.6.22 Embedded Floating-Point Data Interrupt
[Categories: SPE.Embedded Float Scalar Double, SPE.Embedded Float Scalar Single, SPE.Embedded Float Vector]

The Embedded Floating-Point Data interrupt occurs when no higher priority exception exists (see Section 7.9) and an Embedded Floating-Point Data exception is presented to the interrupt mechanism. The Embedded Floating-Point Data exception causing the interrupt is indicated in the SPEFSCR; these exceptions include Embedded Floating-Point Invalid Operation/Input Error (FINV, FINVH), Embedded Floating-Point Divide By Zero (FDBZ, FDBZH), Embedded Floating-Point Overflow (FOV, FOVH), and Embedded Floating-Point Underflow (FUNF, FUNFH).

When an Embedded Floating-Point Data interrupt occurs, the hardware suppresses the execution of the instruction causing the exception.

SRR0, SRR1, MSR, and ESR are updated as follows:

- **SRR0**: Set to the effective address of the instruction causing the Embedded Floating-Point Data interrupt.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.
- **MSR**:
  - CM: MSR_CM is set to EPCRICM.
  - CE, ME, DE: Unchanged
  - VLEMI: Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined MSR bits set to 0.

**ESR**

- SPV: Set to 1.
- VLEMI: Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined ESR bits are set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR_{0,51} || 0x220. Otherwise, instruction execution resumes at address IVPR_{0,47} || IVOR33_{48,59} || 0b0000.

7.6.23 Embedded Floating-Point Round Interrupt
[Categories: SPE.Embedded Float Scalar Double, SPE.Embedded Float Scalar Single, SPE.Embedded Float Vector]

The Embedded Floating-Point Round interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190), SPEFSRCFINXE is set to 1, and any of the following occurs:

- the unrounded result of an Embedded Floating-Point operation is not exact
- an overflow occurs and overflow exceptions are disabled (FOVF or FOVFH is set to 1 and FOVFE is set to 0)
- an underflow occurs and underflow exceptions are disabled (FUNF is set to 1 and FUNFE is set to 0).

The value of SPEFSRCFINXS is 1, indicating that one of the above exceptions has occurred, and additional information about the exception is found in SPEFSRCFGH FG FXH FX.

When an Embedded Floating-Point Round interrupt occurs, the hardware completes the execution of the instruction causing the exception and writes the result to the destination register prior to taking the interrupt.

SRR0, SRR1, MSR, and ESR are updated as follows:

- **SRR0**: Set to the effective address of the instruction following the instruction causing the Embedded Floating-Point Round interrupt.
- **SRR1**: Set to the contents of the MSR at the time of the interrupt.
- **MSR**:
  - CM: MSR_CM is set to EPCRICM.
  - CE, ME, DE: Unchanged
  - VLEMI: Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined MSR bits set to 0.

**ESR**

- SPV: Set to 1.
- VLEMI: Set to 1 if the instruction causing the interrupt resides in VLE storage.

All other defined ESR bits are set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR_{0,51} || 0x240. Otherwise, instruction execution resumes at address IVPR_{0,47} || IVOR34_{48,59} || 0b0000.
7.6.24 Performance Monitor Interrupt [Category: Embedded.Performance Monitor]

The Performance Monitor interrupt is part of the optional Performance Monitor facility; see Appendix D.

7.6.25 Processor Doorbell Interrupt [Category: Embedded.Processor Control]

A Processor Doorbell Interrupt occurs when no higher priority exception exists, a Processor Doorbell exception is present, and the interrupt is enabled (MSRCE=1). Processor Doorbell exceptions are generated when DBELL messages (see Section 11) are received and accepted by the thread.

If Category: Embedded.Hypervisor is supported, the interrupt is enabled if MSRGS = 1 or MSRCE=1.

CSRR0, CSRR1 and MSR are updated as follows:

CSRR0 Set to the effective address of the next instruction to be executed.
CSRR1 Set to the contents of the MSR at the time of the interrupt.

MSR
CM MSR CM is set to EPCRICM.
ME Unchanged.
DE Unchanged if category E.ED is supported, otherwise set to 0.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x280. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3648:59|| 0b0000.

7.6.26 Processor Doorbell Critical Interrupt [Category: Embedded.Processor Control]

A Processor Doorbell Critical Interrupt occurs when no higher priority exception exists, a Processor Doorbell Critical exception is present, and the interrupt is enabled (MSRCE=1). Processor Doorbell Critical exceptions are generated when DBELL_CRIT messages (see Section 11) are received and accepted by the thread.

If Category: Embedded.Hypervisor is supported, the interrupt is enabled if MSRGS = 1 or MSRCE=1.

CSRR0, CSRR1 and MSR are updated as follows:

CSRR0 Set to the effective address of the next instruction to be executed.
CSRR1 Set to the contents of the MSR at the time of the interrupt.

MSR
CM MSR CM is set to EPCRICM.
ME Unchanged.
DE Unchanged if category E.ED is supported, otherwise set to 0.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x2A0. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3748:59|| 0b0000.

7.6.27 Guest Processor Doorbell Interrupt [Category: Embedded.Hypervisor,Embedded.Processor Control]

A Guest Processor Doorbell Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell exception is present, and the interrupt is enabled (MSRGSE=1). Guest Processor Doorbell exceptions are generated when G_DBELL messages (see Section 11) are received and accepted by the thread.

Programming Note

If an implementation does not support ±Infinity rounding modes and the rounding mode is set to be +Infinity or -Infinity, an Embedded Floating-Point Round interrupt occurs after every Embedded Floating-Point instruction for which rounding might occur regardless of the value of FINXE, provided no higher priority exception exists.

When an Embedded Floating-Point Round interrupt occurs, the unrounded (truncated) result of an inexact high or low element is placed in the target register. If only a single element is inexact, the other exact element is updated with the correctly rounded result, and the FG and FX bits corresponding to the other exact element will both be 0.

The bits FG (FGH) and FX (FXH) are provided so that an interrupt handler can round the result as it desires. FG (FGH) is the value of the bit immediately to the right of the least significant bit of the destination format mantissa from the infinitely precise intermediate calculation before rounding. FX (FXH) is the value of the ‘or’ of all the bits to the right of the FG (FGH) of the destination format mantissa from the infinitely precise intermediate calculation before rounding.

If an implementation does not support ±Infinity rounding modes and the rounding mode is set to be +Infinity or -Infinity, an Embedded Floating-Point Round interrupt occurs after every Embedded Floating-Point instruction for which rounding might occur regardless of the value of FINXE, provided no higher priority exception exists.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x280. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3648:59|| 0b0000.

CE, ME,DE
Unchanged.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x280. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3648:59|| 0b0000.
GSRR0, GSRR1 and MSR are updated as follows:

**GSRR0**
Set to the effective address of the next instruction to be executed.

**GSRR1**
Set to the contents of the MSR at the time of the interrupt.

**MSR**
- **CM**: MSR\(_{CM}\) is set to EPCR\(_{CM}\).
- **CE, ME, DE**: Unchanged.
- All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR\(_{0:51}\) || 0x2C0. Otherwise, instruction execution resumes at address IVPR\(_{0:47}\) || IVOR\(_{38:59}\)|| 0b0000.

--- Programming Note ---

Guest Processor Doorbell interrupts are used by the hypervisor to be notified when the guest operating system has set MSR\(_{EE}\) to 1. This allows the hypervisor to reflect base class interrupts to the guest at a time when the guest is ready to accept them (MSR\(_{GS}=1\) and MSR\(_{EE}=1\)).

--- Programming Note ---

Some guest operating systems running on a hypervisor may use lazy interrupt blocking. That is, when the operating system wants to block interrupts at the interrupt controller, it does not actually perform the blocking operation, but instead sets a value in memory that represents the level at which interrupts are to be blocked. When an actual interrupt occurs, this value is consulted to determine if the interrupt should have been blocked. If so, the current interrupt level that is to be blocked is set in the interrupt controller and the interrupt handling code returns without acknowledging the interrupt. When interrupts are unblocked at a later time, the interrupt will be reasserted by the interrupt controller. When a hypervisor is taking external interrupts and then reflecting them to a guest, the hypervisor must acknowledge the interrupt before reflecting it to the guest since the external interrupt will occur again once MSR\(_{GS}=1\) regardless of the state of MSR\(_{EE}\).

To emulate the behavior required for lazy interrupt blocking by the guest, the hypervisor should execute another `msgsnd` instruction specifying a Guest Processor Doorbell at the time that it is reflecting the interrupt to the guest. When the guest performs its interrupt acknowledge (a hypercall or writing to an interrupt controller register emulated by the hypervisor), the hypervisor can execute a `msgclr` to clear a pending message if there are no other interrupts to be reflected to the guest.
Chapter 7. Interrupts and Exceptions

7.6.28 Guest Processor Doorbell Critical Interrupt [Category: Embedded.Hypervisor, Embedded.Processor Control]

A Guest Processor Doorbell Critical Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell Critical exception is present, and the interrupt is enabled (MSRGS = 1 and MSRCE=1). Guest Processor Doorbell Critical exceptions are generated when G_DBELL_CRIT messages (see Section 11) are received and accepted by the thread.

CSRR0, CSRR1 and MSR are updated as follows:

CSRR0 Set to the effective address of the next instruction to be executed.

CSRR1 Set to the contents of the MSR at the time of the interrupt.

MSR

CM MSR_CM is set to EPCR_ICM.
ME Unchanged.
DE Unchanged if category E.ED is supported, otherwise set to 0
All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x2E0. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3948:59|| 0b0000.

Programming Note

Guest Processor Doorbell Critical interrupts are used by the hypervisor to be notified when the guest operating system has set MSRCE to 1. This allows the hypervisor to reflect critical class interrupts to the guest at a time when the guest is ready to accept them (MSRGS=1 and MSRCE=1).

7.6.29 Guest Processor Doorbell Machine Check Interrupt [Category: Embedded.Hypervisor, Embedded.Processor Control]

A Guest Processor Doorbell Machine Check Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell Machine Check exception is present, and the interrupt is enabled (MSRGS = 1 and MSRME=1). Guest Processor Doorbell Machine Check exceptions are generated when G_DBELL_MC messages (see Section 11) are received and accepted by the thread.

CSRR0, CSRR1 and MSR are updated as follows:

CSRR0 Set to the effective address of the next instruction to be executed.

CSRR1 Set to the contents of the MSR at the time of the interrupt.

MSR

CM MSR_CM is set to EPCR_ICM.
ME Unchanged.
DE Unchanged if category E.ED is supported, otherwise set to 0
All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x2E0. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR3948:59|| 0b0000.

Programming Note

Guest Processor Doorbell Machine Check interrupts are used by the hypervisor to be notified when the guest operating system has set MSRME to 1. This allows the hypervisor to reflect machine check class interrupts to the guest at a time when the guest is ready to accept them (MSRGS=1 and MSRME=1).

7.6.30 Embedded Hypervisor System Call Interrupt [Category: Embedded.Hypervisor]

An Embedded Hypervisor System Call interrupt occurs when no higher priority exception exists (see Section 7.9) and a System Call (sc) instruction with LEV = 1 is executed.

SRR0, SRR1, and MSR are updated as follows:

SRR0 Set to the effective address of the instruction after the sc instruction.

SRR1 Set to the contents of the MSR at the time of the interrupt.

MSR

CM MSR_CM is set to EPCR_ICM.
VLEMI Set to 1 if the instruction causing the interrupt resides in VLE storage.
CE, ME, DE
Unchanged.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x300. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR4148:59|| 0b0000.

7.6.31 Embedded Hypervisor Privilege Interrupt [Category: Embedded.Hypervisor]

An Embedded Hypervisor Privilege interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and an Embedded Hypervisor Privilege exception is presented to the exception mechanism.

An Embedded Hypervisor Privilege exception occurs when MSRGS = 1 and MSRPR = 0 and execution is attempted of any of the following:

- a hypervisor-privileged instruction
- an mispr or mispr instruction that specifies an SPR that is hypervisor privileged
- a tlbwe instruction and Category: Embedded.Hypervisor.LRAT is not implemented.
- a tlbwe, tlbsrx, or tlibx instruction and EPCR DGTM=1
- a tlbwe instruction that attempts to write a TLB entry for which TLBV=1 and TLBIPROT=1 when MAS0WO=0b00
- a tlbwe instruction that attempts to write a TLB entry when MAS1V=1, MAS1IPROT=1, and MAS0WO=0b00
- a mtpr or mtpr instruction and MSRPPMMP = 1
- a Cache Locking instruction and MSRUClep = 1

An Embedded Hypervisor Privilege exception may occur for the following implementation dependent reasons when MSRGS = 1 and MSRPR = 0 and execution is attempted of any of the following:

- a tlbwe instruction that attempts to write a TLB entry for which TLBV=0 and TLBIPROT=1 when MAS0WO=0b00
- a tlbwe instruction that attempts to write a TLB entry when MAS1V=0, MAS1IPROT=1, and MAS0WO=0b00
- a tlbwe instruction that attempts to write a TLB entry for which TLBIPROT=1 when MAS0WO=0b01
- a tlbwe instruction that attempts to write a TLB entry when MAS1IPROT=1, and MAS0WO=0b01
- a tlbwe instruction that attempts to write a TLB entry to an array that is disallowed by the implementation
- an implementation dependent instruction or SPR which is hypervisor privileged

An Embedded Hypervisor Privilege exception also occurs when execution is attempted of an ehpriv instruction, regardless of the state of the thread.

Execution of the instruction causing the interrupt is suppressed and SRR0, SRR1, and MSR are updated as follows:

**SRR0** Set to the effective address of the instruction causing the Embedded Hypervisor Privilege interrupt.

**SRR1** Set to the contents of the MSR at the time of the interrupt.

**MSR**
- CM MSR CM is set to EPCR ICMM.
- VLEM Set to 1 if the instruction causing the interrupt resides in VLE storage.
- CE, ME, DE Unchanged.

All other defined MSR bits set to 0.

If Interrupt Fixed Offsets [Category: Embedded.Phased-In] are supported, instruction execution resumes at address IVPR0:51 || 0x320. Otherwise, instruction execution resumes at address IVPR0:47 || IVOR4148:59|| 0b0000.

7.6.32 LRAT Error Interrupt [Category: Embedded.Hypervisor.LRAT]

An LRAT Error interrupt occurs when no higher priority exception exists (see Section 7.9 on page 1190) and an LRAT Miss exception is presented to the interrupt mechanism.

An LRAT Miss exception is caused by either of the following:

- A tlbwe instruction is executed in guest supervisor state and the logical page number (RPN specified by MAS7 and MAS3 and page size specified by MAS1TSIZE) does not match any valid entry in the LRAT.
- A Page Table translation is performed and the associated PTEARPN is to be treated as an LPN (the Embedded.Hypervisor category is supported) and the logical page number (RPN based on PTEARPN and page size specified by PTEPS) does not match any valid entry in the LRAT.

When an LRAT Error interrupt occurs, the hardware suppresses the execution of the instruction causing the LRAT Error interrupt.

**SRR0, SRR1, MSR, ESR, and LPER** are updated as follows:

**SRR0** Set to the effective address of the instruction causing the LRAT Error interrupt.

**SRR1** Set to the contents of the MSR at the time of the interrupt.
MSR

CMMSR_{CM} is set to EPCR_{ICM}.
CE, ME, DE Unchanged.

All other defined MSR bits are set to 0.

DEAR

If the LRAT Error interrupt occurred for a Page Table translation, set to the effective address of a byte that is both within the range of the bytes being accessed by the Storage Access or Cache Management instruction, and within the page whose access caused the LRAT Miss exception. Otherwise, undefined.

ESR

FP Set to 1 if the instruction causing the interrupt is a floating-point load or store and the translation of the operand address causes the LRAT Miss exception; otherwise set to 0.
ST Set to 1 if the instruction causing the interrupt is a Store or 'store-class' Cache Management instruction and the translation of the operand address causes the LRAT Miss exception; otherwise set to 0.
AP Set to 1 if the instruction causing the interrupt is an Auxiliary Processor load or store and the translation of the operand address causes the LRAT Miss exception; otherwise set to 0.
SPV Set to 1 if the instruction causing the interrupt is a SPE operation or a Vector operation, the instruction is a Load or Store, and the translation of the operand address causes the LRAT Miss exception; otherwise set to 0.
DATA Set to 1 if the interrupt is due to an LRAT miss resulting from a Page Table translation of a Load, Store or Cache Management operand address; otherwise set to 0.
TLBI Set to 1 if a TLB Ineligible exception occurred during a Page Table translation for the instruction causing the interrupt; otherwise set to 0.
PT Set to 1 if the cause of the interrupt is an LRAT miss exception on a Page Table translation. Set to 0 if the cause of the interrupt is an LRAT miss exception on a tlbwe.
VLEMI Set to 1 if the instruction causing the interrupt resides in VLE storage, the instruction is a Load, Store, or Cache Management instruction, and the translation of the operand address causes the LRAT Miss exception.
EPID Set to 1 if the instruction causing the interrupt is an External Process ID instruction, the instruction is a Load, Store, or Cache Management instruction, and the translation of the operand address causes the LRAT Miss exception; otherwise set to 0.

All other defined ESR bits are set to 0.

LPER

Set to the values of the ARPN and PS fields from the PTE that was used to translate a virtual address for an instruction fetch, Load, Store or Cache Management instruction that caused an LRAT Error interrupt as a result of an LRAT Miss exception.

If Interrupt Fixed Offsets [Category: Embedded,Phased-In] are supported, instruction execution resumes at address IVPR_{0:47} || 0x0340. Otherwise, instruction execution resumes at address IVPR_{0:47} || IVOR42_{48:59} || 0b0000.
7.7 Partially Executed Instructions

In general, the architecture permits load and store instructions to be partially executed, interrupted, and then to be restarted from the beginning upon return from the interrupt. Unaligned Load and Store instructions, or Load Multiple, Store Multiple, Load String, and Store String instructions may be broken up into multiple, smaller accesses, and these accesses may be performed in any order. In order to guarantee that a particular load or store instruction will complete without being interrupted and restarted, software must mark the storage being referred to as Guarded, and must use an elementary (non-string or non-multiple) load or store that is aligned on an operand-sized boundary.

In order to guarantee that Load and Store instructions can, in general, be restarted and completed correctly without software intervention, the following rules apply when an execution is partially executed and then interrupted:

- For an elementary Load, no part of the target register RT or FRT, will have been altered.
- For ‘with update’ forms of Load or Store, the update register, register RA, will not have been altered.

On the other hand, the following effects are permissible when certain instructions are partially executed and then restarted:

- For any Store, some of the bytes at the target storage location may have been altered (if write access to that page in which bytes were altered is permitted by the access control mechanism). In addition, for Store Conditional instructions, CR0 has been set to an undefined value, and it is undefined whether the reservation has been cleared.
- For any Load, some of the bytes at the addressed storage location may have been accessed (if read access to that page in which bytes were accessed is permitted by the access control mechanism).
- For Load Multiple or Load String, some of the registers in the range to be loaded may have been altered. Including the addressing registers (RA, and possibly RB) in the range to be loaded is a programming error, and thus the rules for partial execution do not protect against overwriting of these registers.

In no case will access control be violated.

As previously stated, the only load or store instructions that are guaranteed to not be interrupted after being partially executed are elementary, aligned, guarded loads and stores. All others may be interrupted after being partially executed. The following list identifies the specific instruction types for which interruption after partial execution may occur, as well as the specific interrupt types that could cause the interruption:

1. Any Load or Store (except elementary, aligned, guarded):
   - Any asynchronous interrupt
   - Machine Check
   - Program (Imprecise Mode Floating-Point Enabled)
   - Program (Imprecise Mode Auxiliary Processor Enabled)

2. Unaligned elementary Load or Store, or any multiple or string:
   - All of the above listed under item 1, plus the following:
     - Data Storage (if the access crosses a protection boundary)
     - Debug (Data Address Compare)

3. mtcrf may also be partially executed due to the occurrence of any of the interrupts listed under item 1 at the time the mtcrf was executing.
   - All instructions prior to the mtcrf have completed execution. (Some storage accesses generated by these preceding instructions may not have completed.)
   - No subsequent instruction has begun execution.
   - The mtcrf instruction (the address of which was saved in SRR0/CSRR0/MCSR0/DSRR0 [Category: Embedded.Enhanced Debug] at the occurrence of the interrupt), may appear not to have begun or may have partially executed.
7.8 Interrupt Ordering and Masking

It is possible for multiple exceptions to exist simultaneously, each of which could cause the generation of an interrupt. Furthermore, for interrupts classes other than the Machine Check interrupt and critical interrupts, the architecture does not provide for reporting more than one interrupt of the same class (unless the Embedded.Enhanced Debug category is supported). Therefore, the architecture defines that interrupts are ordered with respect to each other, and provides a masking mechanism for certain persistent interrupt types.

When an interrupt is masked (disabled), and an event causes an exception that would normally generate the interrupt, the exception persists as a status bit in a register (which register depends upon the exception type). However, no interrupt is generated. Later, if the interrupt is enabled (unmasked), and the exception status has not been cleared by software, the interrupt due to the original exception event will then finally be generated.

All asynchronous interrupts can be masked. In addition, certain synchronous interrupts can be masked. An example of such an interrupt is the Floating-Point Enabled exception type Program interrupt. The execution of a floating-point instruction that causes the FPCR_FE bit to be set to 1 is considered an exception event, regardless of the setting of MSR_FE0,FE1. If MSR_FE0,FE1 are both 0, then the Floating-Point Enabled exception type of Program interrupt is masked, but the exception persists in the FPCR_FE bit. Later, if the MSR_FE0,FE1 bits are enabled, the interrupt will finally be generated.

The architecture enables implementations to avoid situations in which an interrupt would cause the state information (saved in Save/restore Registers) from a previous interrupt to be overwritten and lost. In order to do this, the architecture defines interrupt classes in a hierarchical manner. At each interrupt class, hardware automatically disables any further interrupts associated with the interrupt class by masking the interrupt enable in the MSR when the interrupt is taken. In addition, each interrupt class masks the interrupt enable in the MSR for each lower class in the hierarchy. The hierarchy of interrupt classes is as follows from highest to lowest:

<table>
<thead>
<tr>
<th>Interrupt Class</th>
<th>MSR Enables Cleared</th>
<th>Save/Restore Registers</th>
</tr>
</thead>
<tbody>
<tr>
<td>Machine Check</td>
<td>ME,DE,CE,EE</td>
<td>MSRRO/1</td>
</tr>
<tr>
<td>Debug¹</td>
<td>DE,CE,EE</td>
<td>DSRR0/1</td>
</tr>
<tr>
<td>Critical</td>
<td>CE,EE</td>
<td>CSRR0/1</td>
</tr>
<tr>
<td>Base</td>
<td>EE</td>
<td>SRR0/1</td>
</tr>
<tr>
<td>Guest &lt;E,HV&gt;</td>
<td>EE</td>
<td>GSRR0/1</td>
</tr>
</tbody>
</table>

¹ The Debug interrupt class is Category: E.ED.

Note: MSR_DS may be cleared when a critical interrupt occurs if Category: E.ED is not supported.

### Figure 71. Interrupt Hierarchy

[Category: Embedded.Hypervisor]

The masking of interrupts is affected by MSR_GS and whether the interrupt is directed to the guest supervisor state or the hypervisor state. In general, interrupts directed to the hypervisor state (with the exception of Guest Processor Doorbell type interrupts), are enabled if MSR_GS = 1 regardless of the value of other MSR enables. Interrupts directed to the guest supervisor state are enabled if the associated MSR enables are set and MSR_GS = 1.

If the Embedded.Enhanced Debug category is not supported (or is supported and is not enabled), then the Debug interrupt becomes a Critical class interrupt and all critical class interrupts will clear DE, CE, and EE in the MSR.

Base Class interrupts that occur as a result of precise exceptions are not masked by the EE bit in the MSR and any such exception that occurs prior to software saving the state of SRR0/1 in a base class exception handler will result in a situation that could result in the loss of state information.

This first step of the hardware clearing the MSR enable bits lower in the hierarchy shown in Figure 71 prevents any subsequent asynchronous interrupts from overwriting the Save/Restore Registers (SRR0/SRR1, CSR0/CSRR1, MCSRR0/MCSRR1, or DSRR0/DSRR1 [Category: Embedded,Enhanced Debug]), prior to software being able to save their contents. Hardware also automatically clears, on any interrupt, MSR_PP,FP,FE0,FE1,IS,DS. The clearing of these bits assists in the avoidance of subsequent interrupts of certain other types. However, guaranteeing that interrupt classes lower in the hierarchy do not occur and thus do not overwrite the Save/Restore Registers (SRR0/SRR1, CSR0/CSRR1, DSRR0/DSRR1 [Category: Embedded,Enhanced Debug], or MCSRR0/MCSRR1) also requires the cooperation of system software. Specifically, system software must avoid the exe-
cution of instructions that could cause (or enable) a subsequent interrupt, if the contents of the Save/Restore Registers (SRR0/SRR1, CSRR0/CSRR1, DSRR0/DSRR1 [Category: Embedded.Enhanced Debug], or MCSRR0/MCSRR1) have not yet been saved.

7.8.1 Guidelines for System Software

The following list identifies the actions that system software must avoid, prior to having saved the Save/Restore Registers' contents:

- Re-enabling an interrupt class that is at the same or a lower level in the interrupt hierarchy. This includes the following actions:
  - Re-enabling of MSR_{EE}
  - Re-enabling of MSR_{CE,EE} in critical class interrupt handlers, and if the Embedded.Enhanced Debug category is not supported, re-enabling of MSR_{DE}.
  - [Category: Embedded.Enhanced Debug] Re-enabling of MSR_{CE,EE,DE} in Debug class interrupt handlers
  - Re-enabling of MSR_{EE,CE,DE,ME} in Machine Check interrupt handlers.

- Branching (or sequential execution) to addresses for which any of the following conditions are true.
  - The address is not mapped by the TLB or the Page Table or is mapped without UX=1 or SX=1 permission.
  - Both the Embedded.Hypervisor LRAT and the Embedded Page.Table category are supported, MSR_{GS}=1, and the effective address is mapped by the Page Table but the LPN is not mapped by the LRAT.

This prevents Instruction Storage, LRAT Error, and Instruction TLB Error interrupts.

- Load, Store or Cache Management instructions to addresses for which any of the following conditions are true.
  - The address is not mapped by the TLB or the Page Table or is mapped without the required access permissions.
  - Both the Embedded.Hypervisor LRAT and the Embedded Page.Table category are supported, MSR_{GS}=1, and the effective address is mapped by the Page Table but the LPN is not mapped by the LRAT.

This prevents Data Storage, LRAT Error, and Data TLB Error interrupts.

- Execution of any floating-point instruction
  - This prevents Floating-Point Unavailable interrupts. Note that this interrupt would occur upon the execution of any floating-point instruction, due to the automatic clearing of MSR_{FP}. However, even if software were to re-enable MSR_{FP}, floating-point instructions must still be avoided in order to prevent Program interrupts due to various possible Program interrupt exceptions (Floating-Point Enabled, Unimplemented Operation).

- Re-enabling of MSR_{PR}
  - This prevents Privileged Instruction exception type Program interrupts. Alternatively, software could re-enable MSR_{PR}, but avoid the execution of any privileged instructions.

- Execution of any Auxiliary Processor instruction
  - This prevents Auxiliary Processor Unavailable interrupts, and Auxiliary Processor Enabled type and Unimplemented Operation type Program interrupts.

- Execution of any Illegal instructions
  - This prevents Illegal Instruction exception type Program interrupts.

- Execution of any instruction that could cause an Alignment interrupt
  - This prevents Alignment interrupts. Included in this category are any string or multiple instructions, and any unaligned elementary load or store instructions. See Section 7.6.7 on page 1170 for a complete list of instructions that may cause Alignment interrupts.

It is not necessary for hardware or software to avoid interrupts higher in the interrupt hierarchy (see Figure 71 on page 1187) from within interrupt handlers (and hence, for example, hardware does not automatically clear MSR_{CE,ME,DE} upon a base class interrupt), since interrupts at each level of the hierarchy use different pairs of Save/Restore Registers to save the instruction address and MSR (i.e. SRR0/SRR1 for base class interrupts, and MCSRR0/MCSRR1,DSRR0/DSRR1 [Category: Embedded.Enhanced Debug], or CSR0/CSR1 for non-base class interrupts). The converse, however, is not true. That is, hardware and software must cooperate in the avoidance of interrupts lower in the hierarchy from occurring within interrupt handlers, even though the these interrupts use different Save/Restore Register pairs. This is because the interrupt higher in the hierarchy may have occurred from within a interrupt handler for an interrupt lower in the hierarchy prior to the interrupt handler having saved the Save/Restore Registers. Therefore, within an interrupt handler, Save/Restore Registers for all interrupts lower in the hierarchy may contain data that is necessary to the system software.
7.8.2 Interrupt Order

The following is a prioritized listing of the various enabled interrupts for which exceptions might exist simultaneously:

1. Synchronous (Non-Debug) Interrupts:
   - Data Storage
   - Instruction Storage
   - Alignment
   - Program
   - Embedded Hypervisor Privilege [Category: Embedded.Hypervisor]
   - Floating-Point Unit Unavailable
   - Auxilliary Processor Unavailable
   - Embedded Floating-Point Unavailable [Category: SP.Embedded Float_*]
   - SPE/Embedded Floating-Point/Vector Unavailable [Category: SP.Embedded Float_*]
   - Embedded Floating-Point Data [Category: SP.Embedded Float_*]
   - Embedded Floating-Point Round [Category: SP.Embedded Float_*]
   - System Call
   - Embedded Hypervisor System Call [Category: Embedded.Hypervisor]
   - Data TLB Error
   - Instruction TLB Error
   - LRAT Error [Category: Embedded.Hypervisor.LRAT]

Only one of the above types of synchronous interrupts may have an existing exception generating it at any given time. This is guaranteed by the exception priority mechanism (see Section 7.9 on page 1190) and the requirements of the Sequential Execution Model.

2. Machine Check

4. Debug

5. Critical Input

6. Watchdog Timer

7. Guest Watchdog Timer [Category: Embedded.Hypervisor]

8. Processor Doorbell Critical [Category: Embedded.Processor Control]

10. External Input Category: Embedded.Processor Control

11. Fixed-Interval Timer Category: Embedded.Processor Control

13. Decrementer Category: Embedded.Processor Control

15. Processor Doorbell [Category: Embedded.Processor Control]

17. Embedded Performance Monitor

Even though, as indicated above, the base, synchronous exception types listed under item 1 are generated with higher priority than the non-base interrupt classes listed in items 2-6, the fact is that these base class interrupts will immediately be followed by the highest priority existing interrupt in items 2-5, without executing any instructions at the base class interrupt handler. This is because the base interrupt classes do not automatically disable the MSR mask bits for the interrupts listed in 2-5. In all other cases, a particular interrupt class from the above list will automatically disable any subsequent interrupts of the same class, as well as all other interrupt classes that are listed below it in the priority order.
7.9 Exception Priorities

All synchronous (precise and imprecise) interrupts are reported in program order, as required by the Sequential Execution Model. The one exception to this rule is the case of multiple synchronous imprecise interrupts. Upon a synchronizing event, all previously executed instructions are required to report any synchronous imprecise interrupt-generating exceptions, and the interrupt will then be generated with all of those exception types reported cumulatively, in both the ESR, and any status registers associated with the particular exception type (e.g. the Floating-Point Status and Control Register).

For any single instruction attempting to cause multiple exceptions for which the corresponding synchronous interrupt types are enabled, this section defines the priority order by which the instruction will be permitted to cause a single enabled exception, thus generating a particular synchronous interrupt. Note that it is this exception priority mechanism, along with the requirement that synchronous interrupts be generated in program order, that guarantees that at any given time, there exists for consideration only one of the synchronous interrupt types listed in item 1 of Section 7.8.2 on page 1189. The exception priority mechanism also prevents certain debug exceptions from existing in combination with certain other synchronous interrupt-generating exceptions.

Because unaligned Load and Store instructions, or Load Multiple, Store Multiple, Load String, and Store String instructions may be broken up into multiple, smaller accesses, and these accesses may be performed in any order. The exception priority mechanism applies to each of the multiple storage accesses in the order they are performed by the implementation.

This section does not define the permitted setting of multiple exceptions for which the corresponding interrupt types are disabled. The generation of exceptions for which the corresponding interrupt types are disabled will have no effect on the generation of other exceptions for which the corresponding interrupt types are enabled. Conversely, if a particular exception for which the corresponding interrupt type is enabled is shown in the following sections to be of a higher priority than another exception, it will prevent the setting of that other exception, independent of whether that other exception’s corresponding interrupt type is enabled or disabled.

Except as specifically noted, only one of the exception types listed for a given instruction type will be permitted to be generated at any given time. The priority of the exception types are listed in the following sections ranging from highest to lowest, within each instruction type.

### Programming Note

Some exception types may even be mutually exclusive of each other and could otherwise be considered the same priority. In these cases, the exceptions are listed in the order suggested by the sequential execution model.

#### 7.9.1 Exception Priorities for Defined Instructions

#### 7.9.1.1 Exception Priorities for Defined Floating-Point Load and Store Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any defined Floating-Point Load and Store instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error for instruction fetch [Categories: E.PT and E.HVLRT]
5. Program (Illegal Instruction)
6. Program (Privileged Instruction)
7. Floating-Point Unavailable
8. Program (Unimplemented Operation)
9. Data TLB Error
10. Data Storage (all types)
11. Alignment
12. LRAT Error for data access [Categories: E.PT and E.HVLRT]
13. Debug (Data Address Compare)
14. Debug (Instruction Complete)

If the instruction is causing both a Debug (Instruction Address Compare) and a Debug (Data Address Compare), and is not causing any of the exceptions listed in items 2-11, it is permissible for both exceptions to be generated and recorded in the DBSR. A single Debug interrupt will result.

#### 7.9.1.2 Exception Priorities for Other Defined Load and Store Instructions and Defined Cache Management Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any other defined Load or Store instruction, or defined Cache Management instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error for instruction fetch [Categories: E.PT and E.HVLRT]
5. Program (Illegal Instruction)
6. Program (Privileged Instruction)
Chapter 7. Interrupts and Exceptions

7. Program (Unimplemented Operation)
8. Embedded Hypervisor Privilege [Category: E.HV]
9. Data TLB Error
10. Data Storage (all types)
11. Alignment
12. LRAT Error for data access [Categories: E.PT and E.HV.LRAT]
13. Debug (Data Address Compare)
14. Debug (Instruction Complete)

If the instruction is causing both a Debug (Instruction Address Compare) and a Debug (Data Address Compare), and is not causing any of the exceptions listed in items 2-11, it is permissible for both exceptions to be generated and recorded in the DBSR. A single Debug interrupt will result.

7.9.1.3 Exception Priorities for Other Defined Floating-Point Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any defined floating-point instruction other than a load or store.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Floating-Point Unavailable
7. Program (Unimplemented Operation)
8. Program (Floating-point Enabled)
9. Debug (Instruction Complete)

7.9.1.4 Exception Priorities for Defined Privileged Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any defined privileged instruction, except dcbi, rfi, and rfc1 instructions.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT] (for hardware tablewalk)
5. Program (Illegal Instruction, except for TLB management instructions with invalid MAS settings, see 9)
6. Program (Privileged Instruction)
7. Program (Unimplemented Operation)
8. Embedded Hypervisor Privilege [Category: E.HV]
9. Program (Illegal Instruction, special case for TLB management instructions with invalid MAS settings)
10. LRAT Error [Category: E.HV.LRAT] (for tlbwe)
11. Debug (Instruction Complete)

For mtmsr, mtspr (DBCR0, DBCR1, DBCR2), mtsspr (TCR), and mtsspr (TSR), if they are not causing Debug (Instruction Address Compare) nor Program (Privileged Instruction) exceptions, it is possible that they are simultaneously enabling (via mask bits) multiple existing exceptions (and at the same time possibly causing a Debug (Instruction Complete) exception). When this occurs, the interrupts will be handled in the order defined by Section 7.8.2 on page 1189.

7.9.1.5 Exception Priorities for Defined Trap Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of a defined Trap instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Program (Unimplemented Operation)
7. Debug (Trap)
8. Program (Trap)
9. Debug (Instruction Complete)

If the instruction is causing both a Debug (Instruction Address Compare) and a Debug (Trap), and is not causing any of the exceptions listed in items 2-6, it is permissible for both exceptions to be generated and recorded in the DBSR. A single Debug interrupt will result.

7.9.1.6 Exception Priorities for Defined System Call Instruction

The following prioritized list of exceptions may occur as a result of the attempted execution of a defined System Call instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Program (Unimplemented Operation)
7. System Call
8. Embedded Hypervisor System Call [Category: E.HV]
9. Debug (Instruction Complete)

7.9.1.7 Exception Priorities for Defined Branch Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any defined branch instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Program (Unimplemented Operation)
7. Debug (Branch Taken)
8. Debug (Instruction Complete)

If the instruction is causing both a Debug (Instruction Address Compare) and a Debug (Branch Taken), and is not causing any of the exceptions listed in items 2-6, it is permissible for both exceptions to be generated and recorded in the DBSR. A single Debug interrupt will result.

7.9.1.8 Exception Priorities for Defined Return From Interrupt Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of an rfi, rfci, rfmci, rfdi [Category: Embedded,Enhanced Debug], rfgi [Category: Embedded,Hypervisor] instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Program (Privileged Instruction)
7. Program (Unimplemented Operation)
8. Debug (Return From Interrupt)
9. Debug (Instruction Complete)

If the rfi or rfci, rfmci, or rfdi [Category: Embedded,Enhanced Debug] or rfgi [Category: Embedded,Hypervisor] instruction is causing both a Debug (Instruction Address Compare) and a Debug (Return From Interrupt), and is not causing any of the exceptions listed in items 2-6, it is permissible for both exceptions to be generated and recorded in the DBSR. A single Debug interrupt will result.

7.9.1.9 Exception Priorities for Other Defined Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of all other instructions not listed above.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. LRAT Error instruction fetch [Categories: E.PT and E.HV.LRAT]
5. Program (Illegal Instruction)
6. Program (Privileged Instruction)
7. Program (Unimplemented Operation)

7.9.2 Exception Priorities for Reserved Instructions

The following prioritized list of exceptions may occur as a result of the attempted execution of any reserved instruction.

1. Debug (Instruction Address Compare)
2. Instruction TLB Error
3. Instruction Storage Interrupt (all types)
4. Program (Illegal Instruction)
Chapter 8. Reset and Initialization

8.1 Background

This chapter describes the requirements for thread reset. This includes both the means of causing reset, and the specific initialization that is required to be performed automatically by the hardware. This chapter also provides an overview of the operations that should be performed by initialization software.

In general, the specific actions taken by a thread upon reset are implementation-dependent. Also, it is the responsibility of system initialization software to initialize the majority of thread and system resources after reset. Implementations are required to provide a minimum thread initialization such that this system software may be fetched and executed, thereby accomplishing the rest of system initialization.

8.2 Reset Mechanisms

This specification defines two mechanisms for internally invoking a thread reset operation using either the Watchdog Timer (see Section 9.11 on page 1208) or the Debug facilities using DBCR0RST (see Section 10.5.1.1 on page 1221). In addition, implementations will typically provide additional means for invoking a reset operation, using an external mechanism such as a signal pin, which when activated, causes the thread to be reset.

8.3 Thread State after Reset

The initial thread state is controlled by the register contents after reset. In general, the contents of most registers are undefined after reset.

The hardware is only guaranteed to initialize those registers (or specific bits in registers) which must be initialized in order for software to be able to reliably perform the rest of system initialization.

The Thread Enable Register, Machine State Register, Processor Version Register, and a TLB entry are updated as follows.

**Figure 73. TLB Initial Values**

The initial settings of EPN and RPN are dependent upon the number of bits implemented in the EPN and RPN fields and the minimum page size supported by the implementation. For example, an implementation that supports 64KB pages as the smallest size and 32 bits of effective address would implement a 16 bit EPN and set the initial value of the EPN field of the TLB boot entry to 2^{16}.1 (0xFFFF) while an implementation that supports 4K pages as the smallest size and 32 bits of effective address would implement a 20 bit EPN and
set the initial value of the boot entry to \(2^{20} - 1\) (0xFFFFF).

Instruction execution begins at the last word address of the page mapped by the boot TLB entry. Note that this address is different from the System Reset interrupt vector specified in Book III-S.

An implementation may provide additional methods for initializing the TLB entry used for initial boot by providing an implementation-dependent RPN, or initializing other TLB entries.

If Category: Embedded Multi-threading.Thread Management is not supported, instruction execution for other threads begins at the last word address of the effective address space; otherwise execution begins at the address specified by the NIA register corresponding to the thread.

### 8.4 Software Initialization Requirements

When reset occurs, the thread is initialized to a minimum configuration to start executing initialization code. Initialization code is necessary to complete the thread and system configuration. The initialization code described in this section is the minimum recommended for configuring the thread to run application code.

Initialization code should configure the following resources:

- Invalidate the instruction cache and data cache (implementation-dependent).
- Initialize system memory as required by the operating system or application code.
- Initialize the Interrupt Vector Prefix Register and Interrupt Vector Offset Register.
- Initialize other registers as needed by the system.
- Initialize off-chip system facilities.
- Dispatch the operating system or application code.
Chapter 9. Timer Facilities

9.1 Overview

The Time Base, Decrementer, Fixed-interval Timer, and Watchdog Timer provide timing functions for the system. The remainder of this section describes these registers and related facilities.

9.2 Time Base (TB)

The Time Base (TB) is a 64-bit register (see Figure 74) containing a 64-bit unsigned integer that is incremented periodically. Each increment adds 1 to the low-order bit (bit 63). The frequency at which the integer is updated is implementation-dependent.

Figure 74. Time Base

The Time Base bits 0:59 increment until their value becomes 0xFFF_FFFF_FFFF_FFFF (2^{59} - 1), at the next increment their value becomes 0x000_0000_0000_0000. There is no interrupt or other indication when this occurs.

Time base bits 60:63 may increment at a variable rate. When the value of bit 59 changes, bits 60:63 are set to zero; if bits 60:63 increment to 0xF before the value of bit 59 changes, they remain at 0xF until the value of bit 59 changes.

The period of the Time Base depends on the driving frequency. As an order of magnitude example, suppose that the CPU clock is 1 GHz and that the Time Base is driven by this frequency divided by 32. Then the period of the Time Base would be

\[
T_{TB} = \frac{2^{64} \times 32}{1 \text{ GHz}} = 5.90 \times 10^{11} \text{ seconds}
\]

which is approximately 18,700 years.

The Time Base is implemented such that:

1. Loading a GPR from the Time Base has no effect on the accuracy of the Time Base.

2. Copying the contents of a GPR to the Time Base replaces the contents of the Time Base with the contents of the GPR.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock in a Power ISA system. The Time Base update frequency is not required to be constant. What is required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base bits 0:59 changes, and a means to determine what the current update frequency is.

- The update frequency of the Time Base bits 0:59 is under the control of the system software.

Implementations must provide a means for either preventing the Time Base from incrementing or preventing it from being read in user mode (MSR_{PR}=1). If the means is under software control, it must be privileged. There must be a method for getting all Time Bases in the system to start incrementing with values that are identical or almost identical.
9.2.1 Writing the Time Base

Writing the Time Base is hypervisor privileged. Reading the Time Base is not privileged, it is discussed in Book II.

It is not possible to write the entire 64-bit Time Base using a single instruction. The `mttbl` and `mttbu` extended mnemonics write the lower and upper halves of the Time Base (TBL and TBU), respectively, preserving the other half. These are extended mnemonics for the `mtspr` instruction; see Appendix B, “Assembler Extended Mnemonics” on page 1245.

The Time Base can be written by a sequence such as:

```
   lwz Rx,upper # load 64-bit value for
   lwz Ry,lower # TB into Rx and Ry
   li  Rz,0
   mttbl Rz  # set TBL to 0
   mttbu Rx  # set TBU
   mttbl Ry  # set TBL
```

Provided that no interrupts occur while the last three instructions are being executed, loading 0 into TBL prevents the possibility of a carry from TBL to TBU while the Time Base is being initialized.

---

**Programming Note**

If software initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from $2^{64}-1$ to 0). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.

See the description of the Time Base in Book II, for ways to compute time of day in POSIX format from the Time Base.

---

**Virtualized Implementation Note**

In virtualized implementations, TBU and TBL are read-only.

---

**Programming Note**

The instructions for writing the Time Base are mode-independent. Thus code written to set the Time Base will work correctly in either 64-bit or 32-bit mode.
9.3 Decrementer

The Decrementer (DEC) is a 32-bit decrementing counter that provides a mechanism for causing a Decrementer interrupt after a programmable delay. The contents of the Decrementer are treated as a signed integer.

Figure 75. Decrementer

Decrementer bits 32:59 count down until their value becomes 0x0000_0000, at the next increment their value becomes 0xFFF_FFFF. Decrementer bits 60:63 may decrement at a variable rate. When the value of bit 59 changes, bits 60:63 are set to 0xF; if bits 60:63 decrement to 0x0 before the value of bit 59 changes, they remain at 0x0 until the value of bit 59 changes.

The Decrementer is driven by the same frequency as the Time Base. The period of the Decrementer will depend on the driving frequency, but if the same values are used as given above for the Time Base (see Section 9.2), and if the Time Base update frequency is constant, the period would be

\[ T_{\text{DEC}} = \frac{2^{32} \times 32}{1 \text{ GHz}} = 137 \text{ seconds}. \]

The Decrementer counts down.

The operation of the Decrementer satisfies the following constraints.

1. The operation of the Time Base and the Decrementer is coherent, i.e., the counters are driven by the same fundamental time base.
2. Loading a GPR from the Decrementer has no effect on the accuracy of the Time Base.
3. Copying the contents of a GPR to the Decrementer replaces the contents of the Decrementer with the contents of the GPR.

9.3.1 Writing and Reading the Decrementer

The contents of the Decrementer can be read or written using the `mfspr` and `mtspr` instructions, both of which are hypervisor privileged. When `mfspr` and `mtspr` are executed in guest supervisor state, the access to the DEC is mapped to the GDEC. Using an extended mnemonic (see Appendix B, “Assembler Extended Mnemonics” on page 1245), the Decrementer can be written from GPR Rx using:

`mtdec Rx`

The Decrementer can be read into GPR Rx using:

`mfdec Rx`

Copying the Decrementer to a GPR has no effect on the Decrementer contents or on the interrupt mechanism.

9.3.2 Decrementer Events

A Decrementer event occurs when a decrement occurs on a Decrementer value of 0x0000_0001.

Upon the occurrence of a Decrementer event, the Decrementer may be reloaded from a 32-bit Decrementer Auto-Reload Register (DECAR). See Section 9.5. Upon the occurrence of a Decrementer event, the Decrementer has the following basic modes of operation.

Decrement to one and stop on zero

If TCR\_ARE=0, TSR\_DIS is set to 1, the value 0x0000_0000 is then placed into the DEC, and the Decrementer stops decrementing.

A Decrementer interrupt occurs when no higher priority interrupt exists, a Decrementer exception exists, and the exception is enabled. If Category: Embedded.Hypervisor is supported, the interrupt is enabled by TCR\_DIE=1 and (MSR\_EE=1 or MSR\_GS=1). Otherwise, the interrupt is enabled by TCR\_DIE=1 and MSR\_EE=1. See Section 7.6.12, “Decrementer Interrupt” on page 1173 for details of register behavior caused by the Decrementer interrupt.

Decrement to one and auto-reload

If TCR\_ARE=1, TSR\_DIS is set to 1, the contents of the Decrementer Auto-Reload Register is then placed into the DEC, and the Decrementer continues decrementing from the reloaded value.

A Decrementer interrupt occurs when no higher priority interrupt exists, a Decrementer exception exists, and the exception is enabled. If Category: Embedded.Hypervisor is supported, the interrupt is enabled by TCR\_DIE=1 and (MSR\_EE=1 or

---

**Programming Note**

In systems that change the Time Base update frequency for purposes such as power management, the Decrementer input frequency will also change. Software must be aware of this in order to set interval timers.

If Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.
MSR_DS=1). Otherwise, the interrupt is enabled by TCR_DSIE=1 and MSR_DSIE=1. See Section 7.6.12, "Decrementer Interrupt" on page 1173 for details of register behavior caused by the Decrementer interrupt.

Forcing the Decrementer to 0 using the \texttt{mtspr} instruction will not cause a Decrementer exception; however, decrementing which was in progress at the instant of the \texttt{mtspr} may cause the exception. To eliminate the Decrementer as a source of exceptions, set TCR_DSIE to 0 (clear the Decrementer Interrupt Enable bit).

If it is desired to eliminate all Decrementer activity, the procedure is as follows:

1. Write 0 to TCR_DSIE. This will prevent Decrementer activity from causing exceptions.
2. Write 0 to TCR_ARE to disable the Decrementer auto-reload.
3. Write 0 to Decrementer. This will halt Decrementer decrementing. While this action will not cause a Decrementer exception to be set in TSRDIS, a near simultaneous decrement may have done so.
4. Write 1 to TSRDIS. This action will clear TSRDIS to 0 (see Section 9.7.1 on page 1204). This will clear any Decrementer exception which may be pending. Because the Decrementer is frozen at zero, no further Decrementer events are possible.

If the auto-reload feature is disabled (TCR_ARE=0), then once the Decrementer decrements to zero, it will stay there until software reloads it using the \texttt{mtspr} instruction.

On reset, TCR_ARE is set to 0. This disables the auto-reload feature.

9.4 Guest Decrementer [Category: Embedded.Hypervisor]

The Guest Decrementer (GDEC) is a 32-bit decrementing counter that provides a mechanism for causing a Guest Decrementer interrupt after a programmable delay. The contents of the Guest Decrementer are treated as a signed integer.

![Figure 76. Guest Decrementer](image)

Guest Decrementer bits 32:59 count down until their value becomes 0x000_0000; at the next increment their value becomes 0xFFFF_FFFF. Guest Decrementer bits 60:63 may decrement at a variable rate. When the value of bit 59 changes, bits 60:63 are set to 0xF; if bits 60:63 decrement to 0x0 before the value of bit 59 changes, they remain at 0x0 until the value of bit 59 changes.

The Guest Decrementer is driven by the same frequency as the Time Base. The period of the Guest Decrementer will depend on the driving frequency, but if the same values are used as given above for the Time Base (see Section 9.2), and if the Time Base update frequency is constant, the period would be

\[ T_{DEC} = \frac{2^{32} \times 32}{1 \text{ GHz}} = 137 \text{ seconds}. \]

The Guest Decrementer counts down.

The operation of the Guest Decrementer satisfies the following constraints.

1. The operation of the Time Base and the Guest Decrementer is coherent, i.e., the counters are driven by the same fundamental time base.
2. Loading a GPR from the Guest Decrementer has no effect on the accuracy of the Time Base.
3. Copying the contents of a GPR to the Guest Decrementer replaces the contents of the Guest Decrementer with the contents of the GPR.

9.4.1 Writing and Reading the Guest Decrementer

The contents of the Decrementer can be read or written using the \texttt{mfspr} and \texttt{mtspr} instructions, both of which are supervisor privileged.

Copying the Guest Decrementer to a GPR has no effect on the Guest Decrementer contents or on the interrupt mechanism.

9.4.2 Guest Decrementer Events

A Guest Decrementer event occurs when a decrement occurs on a Guest Decrementer value of 0x0000_0001.

Upon the occurrence of a Guest Decrementer event, the Guest Decrementer may be reloaded from a 32-bit Guest Decrementer Auto-Reload Register (GDECAR). See see Section 9.6. Upon the occurrence of a Guest Decrementer event, the Guest Decrementer has the following basic modes of operation.

---

**Programming Note**

In systems that change the Time Base update frequency for purposes such as power management, the Guest Decrementer input frequency will also change. Software must be aware of this in order to set interval timers.

If Guest Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.
Decrement to one and stop on zero

If GTCRARE=0, GTSRDIS is set to 1, the value 0x0000_0000 is then placed into the GDEC, and the Guest Decrementer stops decrementing.

A Guest Decrementer interrupt occurs when no higher priority interrupt exists, a Guest Decrementer exception exists, and the exception is enabled. The interrupt is enabled by GTCR DIE=1 and (MSREE=1 or MSRGS=1). See Section 7.6.12, “Decrementer Interrupt” on page 1173 for details of register behavior caused by the Guest Decrementer interrupt.

Decrement to one and auto-reload

If GTCRARE=1, GTSRDIS is set to 1, the contents of the Guest Decrementer Auto-Reload Register is then placed into the GDEC, and the Guest Decrementer continues decrementing from the reloaded value.

A Guest Decrementer interrupt occurs when no higher priority interrupt exists, a Guest Decrementer exception exists, and the exception is enabled. The interrupt is enabled by GTCR DIE=1 and (MSREE=1 or MSRGS=1). See Section 7.6.12, “Decrementer Interrupt” on page 1173 for details of register behavior caused by the Guest Decrementer interrupt.

Forcing the Guest Decrementer to 0 using the mtsp r instruction will not cause a Guest Decrementer exception; however, decrementing which was in progress at the instant of the mtsp r may cause the exception. To eliminate the Guest Decrementer as a source of exceptions, set GTCRDIE to 0 (clear the Guest Decrementer Interrupt Enable bit).

If it is desired to eliminate all Guest Decrementer activity, the procedure is as follows:
1. Write 0 to GTCR DIE. This will prevent Guest Decrementer activity from causing exceptions.
2. Write 0 to GTCRARE to disable the Guest Decrementer auto-reload.
3. Write 0 to Guest Decrementer. This will halt Guest Decrementer decrementing. While this action will not cause a Guest Decrementer exception to be set in GTSRDIS, a near simultaneous decrement may have done so.
4. Write 1 to GTSRDIS. This action will clear GTSRDIS to 0 (see Section 9.8.1 on page 1207). This will clear any Guest Decrementer exception which may be pending. Because the Guest Decrementer is frozen at zero, no further Guest Decrementer events are possible.

If the auto-reload feature is disabled (GTCRARE=0), then once the Guest Decrementer decrements to zero, it will stay there until software reloads it using the mtsp r instruction.

On reset, GTCRARE is set to 0. This disables the auto-reload feature.

Programming Note

mtsp r RT,DEC should be used to read GDEC in guest supervisor state. mtsp r DEC,RS should be used to write GDEC in guest supervisor state.

9.5 Decrementer Auto-Reload Register

The Decrementer Auto-Reload Register is a 32-bit register as shown below.

| DECAR | 32 | 63 |

Figure 77. Decrementer Auto-Reload Register

Bits of the Decrementer Auto-Reload register are numbered 32 (most-significant bit) to 63 (least-significant bit). The Decrementer Auto-Reload Register is provided to support the auto-reload feature of the Decrementer. See Section 9.3.2

The contents of the Decrementer Auto-Reload Register cannot be read. The contents of bits 32:63 of register RS can be written to the Decrementer Auto-Reload Register using the mtsp r instruction.

This register is hypervisor privileged.

9.6 Guest Decrementer Auto-Reload Register [Category:Embedded.Hypervisor]

The Guest Decrementer Auto-Reload Register is a 32-bit register as shown below.

| GDECAR | 32 | 63 |

Figure 78. Guest Decrementer Auto-Reload Register

Bits of the Guest Decrementer Auto-Reload Register are numbered 32 (most-significant bit) to 63 (least-significant bit). The Guest Decrementer Auto-Reload Register is provided to support the auto-reload feature of the Guest Decrementer. See Section 9.4.2.

The contents of the Guest Decrementer Auto-Reload Register cannot be read. The contents of bits 32:63 of register RS can be written to the Guest Decrementer Auto-Reload Register using the mtsp r instruction.

This register is hypervisor privileged.
**Programming Note**

`mtspr DECAR,RS` should be used to write GDE-CAR in guest supervisor state. Hypervisor software should emulate the accesses for the guest.
9.7 Timer Control Register

The Timer Control Register (TCR) is a 32-bit register. Timer Control Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The Timer Control Register controls Decrementer (see Section 9.3), Fixed-Interval Timer (see Section 9.9), and Watchdog Timer (see Section 9.11) options.

The relationship of the Timer facilities to the TCR and TB is shown in the figure below.

This register is hypervisor privileged. In guest supervisor state, the access to the TCR is mapped to the GTCR.

The contents of the TCR can be read using the *mfspr* instruction. The contents of bits 32:63 of register RS can be written to the Timer Control Register using the *mtspr* instruction.

The contents of the TCR are defined below:

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32:33</td>
<td><strong>Watchdog Timer Period</strong> (WP) (see Section 9.11 on page 1208)</td>
</tr>
<tr>
<td></td>
<td>Specifies one of 4 bit locations of the Time Base used to signal a Watchdog Timer exception on a transition from 0 to 1. The 4 Time Base bits that can be specified to serve as the Watchdog Timer period are implementation-dependent.</td>
</tr>
<tr>
<td>34:35</td>
<td><strong>Watchdog Timer Reset Control</strong> (WRC) (see Section 9.11 on page 1208)</td>
</tr>
<tr>
<td></td>
<td>00 No Watchdog Timer reset will occur.</td>
</tr>
<tr>
<td></td>
<td>01-11 Force thread to be reset on second time-out of Watchdog Timer. The exact function of any of these settings is implementation-dependent.</td>
</tr>
<tr>
<td></td>
<td>TCRWRC resets to 0b00.</td>
</tr>
</tbody>
</table>

**Architecture Note**

In previous versions of the architecture, it was not possible for software to clear WRC. That limitation has been removed.

**Watchdog Timer Interrupt Enable** (WIE) (see Section 9.11 on page 1208)

0 Disable Watchdog Timer interrupt
1 Enable Watchdog Timer interrupt

**Decrementer Interrupt Enable** (DIE) (see Section 9.3 on page 1199)

0 Disable Decrementer interrupt
1 Enable Decrementer interrupt

38:39 Fixed-Interval Timer Period (FP) (see Section 9.9 on page 1208)

Specifies one of 4 bit locations of the Time Base used to signal a Fixed-Interval Timer exception on a transition from 0 to 1. The 4 Time Base bits that can be specified to serve as the Fixed-Interval Timer period are implementation-dependent.

40 Fixed-Interval Timer Interrupt Enable (FIE) (see Section 9.9 on page 1208)

0 Disable Fixed-Interval Timer interrupt
1 Enable Fixed-Interval Timer interrupt

41 Auto-Reload Enable (ARE)

0 Disable auto-reload of the Decrementer
1 Enable auto-reload of the Decrementer

Decrementer exception is presented (i.e. TSRDIS is set to 1) when the Decrementer is decremented from a value of 0x0000_0001. The next value placed in the Decrementer is the value 0x0000_0000.

If Category: Embedded.Hypervisor is supported, when (MSR EE=1 or MSR GS=1), TCRDIE=1, and TSRDIS=1, a Decrementer interrupt is taken.

If Category: Embedded.Hypervisor is not supported, when MSR EE=1, TCRDIE=1, and TSRDIS=1, a Decrementer interrupt is taken. Software must reset TSRDIS.

1 Enable auto-reload of the Decrementer

Decrementer exception is presented (i.e. TSRDIS is set to 1) when the Decrementer is decremented from a value of 0x0000_0001. The contents of the Decrementer Auto-Reload Register is placed in the Decrementer. The Decrementer resumes decrementing.

If Category: Embedded.Hypervisor is supported, when (MSR EE=1 or MSR GS=1), TCRDIE=1, and TSRDIS=1, a Decrementer interrupt is taken. If Category: Embedded.Hypervisor is not supported, when MSR EE=1, TCRDIE=1, and TSRDIS=1, a Decrementer interrupt is taken. Software must reset TSRDIS.

42 Implementation-dependent

43:63 Reserved

9.7.1 Timer Status Register

The Timer Status Register (TSR) is a 32-bit register. Timer Status Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The Timer Status Register contains status on timer events and the most recent Watchdog Timer-initiated thread reset.

The Timer Status Register is set via hardware, and read and cleared via software. The contents of the Timer Status Register can be read using the msfpr instruction. Bits in the Timer Status Register can be cleared using the msfpr instruction. Clearing is done by writing bits 32:63 of a General Purpose Register to the Timer Status Register with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the Timer Status Register is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

The contents of the TSR are defined below:

<table>
<thead>
<tr>
<th>Bit(s)</th>

<td>A Decrementer event has occurred. If Category: Embedded.Hypervisor is supported, when (MSR EE=1 or MSR GS=1) and TCRDIE=1, a Decrementer interrupt is taken. If Category: Embedded.Hypervisor is not supported, when MSR EE=1 and TCRDIE=1, a Decrementer interrupt is taken.</td>
</tr>
</tbody>
</table>
37 **Fixed-Interval Timer Interrupt Status** (FIS)  
(see Section 9.9 on page 1208)

0 A Fixed-Interval Timer event has not occurred.
1 A Fixed-Interval Timer event has occurred. If Category: Embedded.Hypervisor is supported, when (MSR EE=1 or MSR GS=1) and TCR FIE=1, a Fixed-Interval Timer interrupt is taken. If Category: Embedded.Hypervisor is not supported, when MSR EE=1 and TCR FIE=1, a Fixed-Interval Timer interrupt is taken.

38:63 Reserved
This register is hypervisor privileged. In guest supervisor state, the access to the TSR is mapped to the GTSR.
9.8 Guest Timer Control Register [Category: Embedded.Hypervisor]

The Guest Timer Control Register (GTCR) is a 32-bit register. Guest Timer Control Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The Guest Timer Control Register controls Guest Decrementer (see Section 9.4), Guest Fixed-Interval Timer (see Section 9.10), and Watchdog Timer (see Section 9.11) options.

The relationship of the Guest Timer facilities to the GTCR and TB is shown in the figure below.

This register is supervisor privileged.

The contents of the Guest Timer Control Register can be read using the \texttt{mfspr} instruction. The contents of bits 32:63 of register RS can be written to the Timer Control Register using the \texttt{mtspr} instruction.

The contents of the GTCR are defined below:

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>

</tbody>
</table>
1 Enable Guest Decrementer interrupt

38:39 Guest Fixed-Interval Timer Period (FP) (see Section 9.9 on page 1208)

Specifies one of 4 bit locations of the Time Base used to signal a Guest Fixed-Interval Timer exception on a transition from 0 to 1. The 4 Time Base bits that can be specified to serve as the Guest Fixed-Interval Timer period are implementation-dependent.

40 Guest Fixed-Interval Timer Interrupt Enable (FIE) (see Section 9.9 on page 1208)

0 Disable Guest Fixed-Interval Timer interrupt
1 Enable Guest Fixed-Interval Timer interrupt

41 Guest Auto-Reload Enable (ARE)

0 Disable auto-reload of the Guest Decrementer

Guest Decrementer exception is presented (i.e. GTSRDIS is set to 1) when the Guest Decrementer is decremented from a value of 0x0000_0001. The next value placed in the Guest Decrementer is the value 0x0000_0000. When (MSRE=1 and MSRGS=1), GTCRDIE=1, and GTSRDIS=1, a Guest Decrementer interrupt is taken. Software must reset GTSRDIS.

1 Enable auto-reload of the Guest Decrementer

Guest Decrementer exception is presented (i.e. GTSRDIS is set to 1) when the Guest Decrementer is decremented from a value of 0x0000_0001. The contents of the Guest Decrementer Auto-Reload Register is placed in the Guest Decrementer. When (MSRE=1 and MSRGS=1), GTCRDIE=1, and GTSRDIS=1, a Guest Decrementer interrupt is taken. Software must reset GTSRDIS.

42 Implementation-dependent

43:63 Reserved

Programming Note

*mspr* RT,TCR should be used to read GTCR in guest supervisor state. *mtspr* TCR,RS should be used to write GTCR in guest supervisor state.

9.8.1 Guest Timer Status Register

[Category: Embedded.Hypervisor]

The Guest Timer Status Register (GTSR) is a 32-bit register. Guest Timer Status Register bits are numbered 32 (most-significant bit) to 63 (least-significant bit). The Guest Timer Status Register contains status on timer events and the most recent Watchdog Timer-initiated thread reset.

The Guest Timer Status Register is set via hardware, and read and cleared via software. The contents of the Guest Timer Status Register can be read using the *mfspr* instruction. Bits in the Guest Timer Status Register can be cleared using the *mtspr* instruction. Clearing is done by writing bits 32:63 of a General Purpose Register to the Guest Timer Status Register with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the Guest Timer Status Register is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

The contents of the GTSR are defined below:

**Bit(s)** | **Description**
--- | ---
32 | Enable Next Guest Watchdog Timer (ENW) (see Section 9.11 on page 1208)
0 | Action on next Guest Watchdog Timer time-out is to set GTSRENW
1 | Action on next Guest Watchdog Timer time-out is governed by GTSRWIS
33 | Guest Watchdog Timer Interrupt Status (WIS) (see Section 9.11 on page 1208)
0 | A Guest Watchdog Timer event has not occurred.
1 | A Guest Watchdog Timer event has occurred. When (MSR CE=1 and MSRGS=1) and GTCRWIE=1, a Guest Watchdog Timer interrupt is taken.
34:35 | Guest Watchdog Timer Reset Status (WRS) (see Section 9.11 on page 1208)
00 | No Guest Watchdog Timer reset has occurred.
01 | Implementation-dependent reset information.
10 | Implementation-dependent reset information.
11 | Implementation-dependent reset information.
36 | Guest Decrementer Interrupt Status (DIS) (see Section 9.4.2 on page 1200)
0 | A Guest Decrementer event has not occurred.
1 | A Guest Decrementer event has occurred. When MSR EE=1 and MSRGS=1 and GTCRDIE=1, a Guest Decrementer interrupt is taken.
37 | Guest Fixed-Interval Timer Interrupt Status (FIS) (see Section 9.10 on page 1208)
0 | A Guest Fixed-Interval Timer event has not occurred.
A Guest Fixed-Interval Timer event has occurred. When (MSR_EE=1 and MSR_GS=1) and GTCR_FIE=1, a Guest Fixed-Interval Timer interrupt is taken.

This register is supervisor privileged.

Programming Note

\texttt{mtspr RT,TSR} should be used to read GTSR in guest supervisor state. \texttt{mtspr TSR,RS} should be used to write GTSR in guest supervisor state.

### 9.8.2 Guest Timer Status Register Write Register (GTSRWR) [Category: Embedded.Hypervisor]

The Guest Timer Status Register Write Register (GTSRWR) allows a hypervisor state program to write the contents of the Guest Timer Status Register (see Section 9.8.1). The format of the GTSRWR is shown in Figure 81 below.

![Figure 81. Guest Timer Status Register Write Register](image)

The GTSRWR is provided as a means to restore the contents of the GTSR on a partition switch.

Writing GTSRWR changes the value in the GTSR. Writing non-zero bits may cause a Guest Decrementer or Fixed-Interval Timer exception.

This register is hypervisor privileged.

Programming Note

Hypervisors must ensure that a partition swap does not cause missing timer events to occur in guests. Upon partition restore, the hypervisor must set the appropriate status conditions in the GTSR.

### 9.9 Fixed-Interval Timer

The Fixed-Interval Timer (FIT) is a mechanism for providing timer interrupts with a repeatable period, to facilitate system maintenance. It is similar in function to an auto-reload Decrementer, except that there are fewer selections of interrupt period available. The Fixed-Interval Timer exception occurs on 0 to 1 transitions of a selected bit from the Time Base (see Section 9.7).

The Fixed-Interval Timer exception is logged by GTSRFIS. A Fixed-Interval Timer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Fixed-Interval Timer exception exists (TSRFIE=1), and the exception is enabled. If category mbedded.Hypervisor is supported, the interrupt is enabled by TCRFIE=1 and (MSRE= 1 or MSRGS=1). Otherwise, the interrupt is enabled by TCRFIE=1 and MSREE=1. See Section 7.6.14 on page 1174 for details of register behavior caused by the Fixed-Interval Timer interrupt.

Note that a Fixed-Interval Timer exception will also occur if the selected Time Base bit transitions from 0 to 1 due to an \texttt{mtspr} instruction that writes a 1 to the bit when its previous value was 0.

### 9.10 Guest Fixed-Interval Timer

[Category: Embedded.Hypervisor]

The Guest Fixed-Interval Timer (FIT) is a mechanism for providing timer interrupts with a repeatable period, to facilitate system maintenance. It is similar in function to an auto-reload Guest Decrementer, except that there are fewer selections of interrupt period available. The Guest Fixed-Interval Timer exception occurs on 0 to 1 transitions of a selected bit from the Time Base (see Section 9.7).

The Guest Fixed-Interval Timer exception is logged by GTSRFIS. A Guest Fixed-Interval Timer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Guest Fixed-Interval Timer exception exists (GTSRFIS=1), and the exception is enabled. The interrupt is enabled by GTCR_FIE=1 and (MSRE = 1 and MSRGS=1). See Section 7.6.14 on page 1174 for details of register behavior caused by the Fixed-Interval Timer interrupt.

Note that a Guest Fixed-Interval Timer exception will also occur if the selected Time Base bit transitions from 0 to 1 due to an \texttt{mtspr} instruction that writes a 1 to the bit when its previous value was 0.

### 9.11 Watchdog Timer

The Watchdog Timer is a facility intended to aid system recovery from faulty software or hardware. Watchdog time-outs occur on 0 to 1 transitions of selected bits from the Time Base (Section 9.7).

When a Watchdog Timer time-out occurs while Watchdog Timer Interrupt Status is clear (TSRWIS = 0) and the next Watchdog Time-out is enabled (TSRENW = 1), a Watchdog Timer exception is generated and logged by setting TSRWIS to 1. This is referred to as a Watchdog Timer First Time Out. A Watchdog Timer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Watchdog Timer excep-
tion exists \( \text{TSRWIS}=1 \), and the exception is enabled. If Category: Embedded.Hypervisor is supported, the interrupt is enabled by \( \text{TCR}_{\text{WIE}}=1 \) and \( \text{MSR}_{\text{CE}} = 1 \) or \( \text{MSR}_{\text{GS}}=1 \). Otherwise, the interrupt is enabled by \( \text{TCR}_{\text{WIE}}=1 \) and \( \text{MSR}_{\text{CE}}=1 \). See Section 7.6.16 on page 1175 for details of register behavior caused by the Watchdog Timer Interrupt. The purpose of the Watchdog Timer First time-out is to give an indication that there may be a problem and give the system a chance to perform corrective action or capture a failure before a reset occurs from the Watchdog Timer Second time-out as explained further below.

Note that a Watchdog Timer exception will also occur if the selected Time Base bit transitions from 0 to 1 due to an \textit{mtspr} instruction that writes a 1 to the bit when its previous value was 0.

When a Watchdog Timer time-out occurs while \( \text{TSRWIS} = 1 \) and \( \text{TSRENW} = 1 \), a thread reset occurs if it is enabled by a non-zero value of the Watchdog Reset Control field in the Timer Control Register (TCR\(_{\text{WRC}}\)). This is referred to as a Watchdog Timer Second Time Out. The assumption is that \( \text{TSRWIS} \) was not cleared because the thread was unable to execute the Watchdog Timer interrupt handler, leaving reset as the only available means to restart the system.

A more complete view of Watchdog Timer behavior is afforded by Figure 82 and Figure 83, which describe the Watchdog Timer state machine and Watchdog Timer controls. The numbers in parentheses in the figure refer to the discussion of modes of operation which follow the table.

---

**Figure 82. Watchdog State Machine**

When a Watchdog Timer time-out occurs while \( \text{TSRWIS} = 1 \) and \( \text{TSRENW} = 1 \), a thread reset occurs if it is enabled by a non-zero value of the Watchdog Reset Control field in the Timer Control Register (TCR\(_{\text{WRC}}\)). This is referred to as a Watchdog Timer Second Time Out. The assumption is that \( \text{TSRWIS} \) was not cleared because the thread was unable to execute the Watchdog Timer interrupt handler, leaving reset as the only available means to restart the system.

A more complete view of Watchdog Timer behavior is afforded by Figure 82 and Figure 83, which describe the Watchdog Timer state machine and Watchdog Timer controls. The numbers in parentheses in the figure refer to the discussion of modes of operation which follow the table.
Figure 83. Watchdog Timer Controls

The controls described in the above table imply three different modes of operation that a programmer might select for the Watchdog Timer. Each of these modes assumes that TCRWRC has been set to allow thread reset by the Watchdog facility:

1. Always take the Watchdog Timer interrupt when pending, and never attempt to prevent its occurrence. In this mode, the Watchdog Timer interrupt caused by a first time-out is used to clear TSRWIS so a second time-out never occurs. TSRENW is not cleared, thereby allowing the next time-out to cause another interrupt.

2. Always take the Watchdog Timer interrupt when pending, but avoid when possible. In this mode a recurring code loop of reliable duration (or perhaps a periodic interrupt handler such as the Fixed-Interval Timer interrupt handler) is used to repeatedly clear TSRWIS such that a first-time-out exception is avoided, and thus no Watchdog Timer interrupt occurs. Once TSRWIS has been cleared, software has between one and two full Watchdog periods before a Watchdog exception will be posted in TSRWIS. If this occurs before the software is able to clear TSNW again, a Watchdog Timer interrupt will occur. In this case, the Watchdog Timer interrupt handler will then clear both TSNW and TSRWIS, in order to (hopefully) avoid the next Watchdog Timer interrupt.

3. Never take the Watchdog Timer interrupt. In this mode, Watchdog Timer interrupts are disabled (via TCRWIE=0), and the system depends upon a recurring code loop of reliable duration (or perhaps a periodic interrupt handler such as the Fixed-Interval Timer interrupt handler) to repeatedly clear TSRWIS such that a second time-out is avoided, and thus no reset occurs. TSRWIS is not cleared, thereby allowing the next time-out to set TSRWIS again. The recurring code loop must have a period which is less than one Watchdog Timer period in order to guarantee that a Watchdog Timer reset will not occur.

9.12 Guest Watchdog Timer

[Category: Embedded.Hypervisor]

The Guest Watchdog Timer is a facility intended to aid system recovery from faulty software or hardware. Guest Watchdog time-outs occur on 0 to 1 transitions of selected bits from the Time Base (Section 9.7).

When a Guest Watchdog Timer time-out occurs while Guest Watchdog Timer Interrupt Status is clear (GTSRWIS = 0) and the next Guest Watchdog Time-out is enabled (GTSRENW = 1), a Guest Watchdog Timer exception is generated and logged by setting GTSRWIS to 1. This is referred to as a Guest Watchdog Timer First Time Out. A Guest Watchdog Timer interrupt occurs when no higher priority interrupt exists (see Section 7.9 on page 1190), a Guest Watchdog Timer exception exists (GTSRWIS=1), and the exception is enabled. The interrupt is enabled by GTCTRWE=1 and (MSRCE = 1 and MSRGS=1). See Section 7.6.17 on page 1176 for details of register behavior caused by the Guest Watchdog Timer Interrupt. The purpose of the Guest Watchdog Timer First-time-out is to give an indication that there may be problem and give the system a chance to perform corrective action or capture a failure before a virtualized reset (a Watchdog Timer exception in the hypervisor) occurs from the Guest Watchdog Timer Second time-out as explained further below.
Note that a Guest Watchdog Timer exception will also occur if the selected Time Base bit transitions from 0 to 1 due to an `mtspr` instruction that writes a 1 to the bit when its previous value was 0.

A Guest Watchdog Timer Second Time Out results when a Guest Watchdog Timer time-out occurs while `GTSRWIS = 1`, `GTSRENW = 1`, and a non-zero value is present in the Guest Watchdog Reset Control field in the Guest Timer Control Register (GTCRWRC). In this case, a Watchdog Timer Interrupt is directed toward the hypervisor and the value set in GTSRWRS reflects the virtualized reset condition. The assumption is that GTSRWIS was not cleared because the guest was unable to execute the Guest Watchdog Timer interrupt handler, leaving a virtualized reset as the only available means to stop or restart the guest.

A more complete view of Guest Watchdog Timer behavior is afforded by Figure 84 and Figure 85, which describe the Guest Watchdog Timer state machine and Guest Watchdog Timer controls. The numbers in parentheses in the figure refer to the discussion of modes of operation which follow the table.

![Figure 84. Guest Watchdog State Machine](image)

<table>

<td>Cause Guest Watchdog Timer virtualized reset action specified by GTCRWRC. Virtualized reset will copy pre-reset GTCRWRC into GTSRWRS, then clear GTCRWRC.</td>
</tr>
</tbody>
</table>

![Figure 85. Guest Watchdog Timer Controls](image)

The controls described in the above table imply three different modes of operation that a programmer might select for the Guest Watchdog Timer. Each of these modes assumes that GTCRWRC has been set on a thread to allow virtualized reset by the Guest Watchdog facility.
1. Always take the Guest Watchdog Timer interrupt when pending, and never attempt to prevent its occurrence. In this mode, the Guest Watchdog Timer interrupt caused by a first time-out is used to clear GTSRWIS so a second time-out never occurs. GTSRENW is not cleared, thereby allowing the next time-out to cause another interrupt.

2. Always take the Guest Watchdog Timer interrupt when pending, but avoid when possible. In this mode a recurring code loop of reliable duration (or perhaps a periodic interrupt handler such as the Guest Fixed-Interval Timer interrupt handler) is used to repeatedly clear GTSRENW such that a first time-out exception is avoided, and thus no Guest Watchdog Timer interrupt occurs. Once GTSRENW has been cleared, software has between one and two full Guest Watchdog periods before a Guest Watchdog exception will be posted in GTSRWIS. If this occurs before the software is able to clear GTSRENW again, a Guest Watchdog Timer interrupt will occur. In this case, the Guest Watchdog Timer interrupt handler will then clear both GTSRENW and GTSRWIS, in order to (hopefully) avoid the next Guest Watchdog Timer interrupt.

3. Never take the Guest Watchdog Timer interrupt. In this mode, Guest Watchdog Timer interrupts are disabled (via GTCRWIE=0), and the system depends upon a recurring code loop of reliable duration (or perhaps a periodic interrupt handler such as the Guest Fixed-Interval Timer interrupt handler) to repeatedly clear GTSRWIS such that a second time-out is avoided, and thus no virtualized reset occurs. GTSRENW is not cleared, thereby allowing the next time-out to set GTSRWIS again. The recurring code loop must have a period which is less than one Guest Watchdog Timer period in order to guarantee that a Guest Watchdog Timer virtualized reset will not occur.

9.13 Freezing the Timer Facilities

The debug mechanism provides a means of temporarily freezing the timers upon a debug event. Whenever a debug event is set in the Debug Status Register, all timers will be frozen by preventing the Time Base from incrementing. This allows a debugger to simulate the appearance of ‘real time’, even though the application has been temporarily ‘halted’ to service the debug event. See the description of bit 63 of the Debug Control Register 0 (Freeze Timers on Debug Event or DBCR0FT) in Section 10.5.1.1 on page 1221.
Chapter 10. Debug Facilities

10.1 Overview

Debug facilities are provided to enable hardware and software debug functions, such as instruction and data breakpoints and program single stepping. The debug facilities consist of a set of Debug Control Registers (DBCR0, DBCR1, and DBCR2) (see Section 10.5.1 on page 1221), a set of Address Compare Registers (IAC1, IAC2, IAC3, IAC4, DAC1, and DAC2), (see Section 10.4.3, Section 10.4.4, and Section 10.4.5), a Debug Status Register (DBSR) (see Section 10.5.2) for enabling and recording various kinds of debug events, and a special Debug interrupt type built into the interrupt mechanism (see Section 7.6.20). The debug facilities also provide a mechanism for software-controlled thread reset, and for controlling the operation of the timers in a debug environment.

The mfspr and mtspr instructions (see Section 5.4.1) provide access to the registers of the debug facilities.

In addition to the facilities described here, implementations will typically include debug facilities, modes, and access mechanisms which are implementation-specific. For example, implementations will typically provide access to the debug facilities via a dedicated interface such as the IEEE 1149.1 Test Access Port (JTAG).

10.2 Internal Debug Mode

Debug events include such things as instruction and data breakpoints. These debug events cause status bits to be set in the Debug Status Register. The existence of a set bit in the Debug Status Register is considered a Debug exception. Debug exceptions, if enabled, will cause Debug interrupts.

There are two different mechanisms that control whether Debug interrupts are enabled. The first is the MSRDE bit, and this bit must be set to 1 to enable Debug interrupts. The second mechanism is an enable bit in the Debug Control Register 0 (DBCR0). This bit is the Internal Debug Mode bit (DBCR0IDM), and it must also be set to 1 to enable Debug interrupts.

When DBCR0IDM = 1, the thread is in Internal Debug Mode. In this mode, debug events will (if also enabled by MSRDE) cause Debug interrupts. Software at the Debug interrupt vector location will thus be given control upon the occurrence of a debug event, and can access (via the normal instructions) all architected resources. In this fashion, debug monitor software can control the thread and gather status, and interact with debugging hardware.

When the thread is not in Internal Debug Mode (DBCR0IDM = 0), debug events may still occur and be recorded in the Debug Status Register. These exceptions may be monitored via software by reading the Debug Status Register (using mfspr), or may eventually cause a Debug interrupt if later enabled by setting DBCR0IDM = 1 (and MSRDE = 1). Behavior when debug events occur while DBCR0IDM = 0 is implementation-dependent.

10.3 External Debug Mode [Category: Embedded.Enhanced Debug]

The External Debug Mode is a mode in which external facilities can control execution and access registers and other resources. These facilities are defined as the external debug facilities and are not defined here, however some instructions and registers share internal and external debug roles and are briefly described as necessary.

A dnh instruction is provided to stop instruction fetching and execution and allow the thread to be managed by an external debug facility. After the dnh instruction is executed, instructions are not fetched, interrupts are not taken, and the thread does not execute instructions.

10.4 Debug Events

Debug events are used to cause Debug exceptions to be recorded in the Debug Status Register (see Section 10.5.2). In order for a debug event to be enabled to set a Debug Status Register bit and thereby
cause a Debug exception, the specific event type must be enabled by a corresponding bit or bits in the Debug Control Register DBCR0 (see Section 10.5.1.1), DBCR1 (see Section 10.5.1.2), or DBCR2 (see Section 10.5.1.3), in most cases; the Unconditional Debug Event (UDE) is an exception to this rule. Once a Debug Status Register bit is set, if Debug interrupts are enabled by MSRDE, a Debug interrupt will be generated.

To prevent spurious hypervisor debug events from occurring when a guest has been permitted to use the Debug facilities, if the thread is in hypervisor state (MSRDE=0) and debug events are disabled for hypervisor (EPCRDUVD=1), no debug events are allowed to occur except for the Unconditional Debug Event. It is implementation-dependent whether the Unconditional Debug Event is allowed to occur in hypervisor state when EPCRDUVD=1.

Certain debug events are not allowed to occur when MSRDE=0. In such situations, no Debug exception occurs and thus no Debug Status Register bit is set. Other debug events may cause Debug exceptions and set Debug Status Register bits regardless of the state of MSRDE. The associated Debug interrupts that result from such Debug exceptions will be delayed until MSRDE=1, provided the exceptions have not been cleared from the Debug Status Register in the meantime.

Any time that a Debug Status Register bit is allowed to be set while MSRDE=0, a special Debug Status Register bit, Imprecise Debug Event (DBSR_IDE), will also be set. DBSR_IDE indicates that the associated Debug exception bit in the Debug Status Register was set while Debug interrupts were disabled via the MMSRDE bit. Debug interrupt handler software can use this bit to determine whether the address recorded in CSRR0/DSRR0 should be interpreted as the address associated with the instruction causing the Debug exception, or simply the address of the instruction after the one which set the MSRDE bit, thereby enabling the delayed Debug interrupt.

Debug interrupts are ordered with respect to other interrupt types (see Section 7.8 on page 179). Debug exceptions are prioritized with respect to other exceptions (see Section 7.9 on page 183).

There are eight types of debug events defined:

1. Instruction Address Compare debug events
2. Data Address Compare debug events
3. Trap debug events
4. Branch Taken debug events
5. Instruction Complete debug events
6. Interrupt Taken debug events
7. Return debug events
8. Unconditional debug events
9. Critical Interrupt Taken debug events [Category: Embedded.Enhanced Debug]
10. Critical Interrupt Return debug events [Category: Embedded.Enhanced Debug]
There are two classes of debug exception types:

Type 1: exception before instruction

Type 2: exception after instruction

Almost all debug exceptions fall into the first type. That is, they all take the interrupt upon encountering an instruction having the exception without updating any architectural state (other than DBSR, CSRR0/DSRR0 [Category: Embedded.Enhanced Debug], CSRR1/DSRR1 [Category: Embedded.Enhanced Debug], MSR) for that instruction.

The CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] for this type of exception points to the instruction that encountered the exception. This includes IAC, DAC, branch taken, etc.

The only exception which fall into the second type is the instruction complete debug exception. This exception is taken upon completing and updating one instruction and then pointing CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] to the next instruction to execute.

To make forward progress for any Type 1 debug exception one does the following:

1. Software sets up Type 1 exceptions (e.g. branch taken debug exceptions) and then returns to normal program operation
2. Hardware takes Debug interrupt upon the first branch taken Debug exception, pointing to the branch with CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] to the next instruction to execute.
3. Software, in the debug handler, sees the branch taken exception type, does whatever logging/analysis it wants to, then clears all debug event enables in the DBCR except for the instruction complete debug event enable.
4. Software does an rfci or rfdi [Category: Embedded.Enhanced Debug].
5. Hardware would execute and complete one instruction (the branch taken in this case), and then take a Debug interrupt with CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] pointing to the target of the branch.
6. Software would see the instruction complete interrupt type. It clears the instruction complete event enable, then enables the branch taken interrupt event again.
7. Software does an rfci or rfdi [Category: Embedded.Enhanced Debug].
8. Hardware resumes on the target of the taken branch and continues until another taken branch, in which case we end up at step 2 again.

This, at first, seems like a double tax (i.e. 2 debug interrupts for every instance of a Type 1 exception), but there doesn't seem like any other clean way to make forward progress on Type 1 debug exceptions. The only other way to avoid the double tax is to have the debug handler routine actually emulate the instruction pointed to for the Type 1 exceptions, determine the next instruction that would have been executed by the interrupted program flow and load the CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] with that address and do an rfci/rfdi [Category: Embedded.Enhanced Debug]; this is probably not faster.

10.4.1 Instruction Address Compare Debug Event

One or more Instruction Address Compare debug events (IAC1, IAC2, IAC3 or IAC4) occur if they are enabled and execution is attempted of an instruction at an address that meets the criteria specified in the DBCR0, DBCR1, IAC1, IAC2, IAC3, and IAC4 Registers.

Instruction Address Compare User/Supervisor Mode

DBCR1IAC1US specifies whether IAC1 debug events can occur in user mode or supervisor mode, or both.

DBCR1IAC2US specifies whether IAC2 debug events can occur in user mode or supervisor mode, or both.

DBCR1IAC3US specifies whether IAC3 debug events can occur in user mode or supervisor mode, or both.

DBCR1IAC4US specifies whether IAC4 debug events can occur in user mode or supervisor mode, or both.

Effective/Real Address Mode

DBCR1IAC1ER specifies whether effective addresses, real addresses, effective addresses and MSR1S=0, or effective addresses and MSR1S=1 are used in determining an address match on IAC1 debug events.

DBCR1IAC2ER specifies whether effective addresses, real addresses, effective addresses and MSR1S=0, or
effective addresses and MSR$_{IS}=1$ are used in determining an address match on IAC2 debug events.

DBCR$_{IAC3ER}$ specifies whether effective addresses, real addresses, effective addresses and MSR$_{IS}=0$, or effective addresses and MSR$_{IS}=1$ are used in determining an address match on IAC3 debug events.

DBCR$_{IAC4ER}$ specifies whether effective addresses, real addresses, effective addresses and MSR$_{IS}=0$, or effective addresses and MSR$_{IS}=1$ are used in determining an address match on IAC4 debug events.

### Instruction Address Compare Mode

DBCR$_{IAC12M}$ specifies whether all or some of the bits of the address of the instruction fetch must match the contents of the IAC1 or IAC2, whether the address must be inside a specific range specified by the IAC1 and IAC2 or outside a specific range specified by the IAC1 and IAC2 for an IAC1 or IAC2 debug event to occur.

DBCR$_{IAC34M}$ specifies whether all or some of the bits of the address of the instruction fetch must match the contents of the IAC3 Register or IAC4 Register, whether the address must be inside a specific range specified by the IAC3 Register and IAC4 Register or outside a specific range specified by the IAC3 Register and IAC4 Register for an IAC3 or IAC4 debug event to occur.

There are four instruction address compare modes.

#### Exact address compare mode

If the address of the instruction fetch is equal to the value in the enabled IAC Register, an instruction address match occurs. For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

#### Address bit match mode

For IAC1 and IAC2 debug events, if the address of the instruction fetch access, ANDed with the contents of the IAC2, are equal to the contents of the IAC1, also ANDed with the contents of the IAC2, an instruction address match occurs.

For IAC3 and IAC4 debug events, if the address of the instruction fetch, ANDed with the contents of the IAC4, are equal to the contents of the IAC3, also ANDed with the contents of the IAC4, an instruction address match occurs.

For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

#### Inclusive address range compare mode

For IAC1 and IAC2 debug events, if the 64-bit address of the instruction fetch is greater than or equal to the contents of the IAC1 and less than the contents of the IAC2, an instruction address match occurs.

For IAC3 and IAC4 debug events, if the 64-bit address of the instruction fetch is greater than or equal to the contents of the IAC3 and less than the contents of the IAC4, an instruction address match occurs.

- For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

### Exclusive address range compare mode

For IAC1 and IAC2 debug events, if the 64-bit address of the instruction fetch is less than the contents of the IAC1 or greater than or equal to the contents of the IAC2, an instruction address match occurs.

For IAC3 and IAC4 debug events, if the 64-bit address of the instruction fetch is less than the contents of the IAC3 or greater than or equal to the contents of the IAC4, an instruction address match occurs.

For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

See the detailed description of DBCR0 (see Section 10.5.1.1, “Debug Control Register 0 (DBCR0)” on page 1221) and DBCR1 (see Section 10.5.1.2, “Debug Control Register 1 (DBCR1)” on page 1222) and the modes for detecting IAC1, IAC2, IAC3 and IAC4 debug events. Instruction Address Compare debug events can occur regardless of the setting of MSR$_{DE}$ or DBCR0$_{IDM}$.

When an Instruction Address Compare debug event occurs, the corresponding DBSR$_{IAC1}$, DBSR$_{IAC2}$, DBSR$_{IAC3}$, or DBSR$_{IAC4}$ bit or bits are set to record the debug exception. If MSR$_{DE}=0$, DBSR$_{IDE}$ is also set to 1 to record the imprecise debug event.

If MSR$_{DE}=1$ (i.e. Debug interrupts are enabled) at the time of the Instruction Address Compare debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt). The execution of the instruction causing the exception will be suppressed, and CSRR0/DSRR0 [Category: Embedded. Enhanced Debug] will be set to the address of the excepting instruction.

If MSR$_{DE}=0$ (i.e. Debug interrupts are disabled) at the time of the Instruction Address Compare debug exception, a Debug interrupt will not occur, and the instruction will complete execution (provided the instruction is not causing some other exception which will generate an enabled interrupt).
Later, if the debug exception has not been reset by clearing DBSR\textsubscript{IAC1}, DBSR\textsubscript{IAC2}, DBSR\textsubscript{IAC3}, and DBSR\textsubscript{IAC4}, and MSR\textsubscript{DE} is set to 1, a delayed Debug interrupt will occur. In this case, CSRR\textsubscript{0}/DSRR\textsubscript{0} will contain the address of the instruction after the one which enabled the Debug interrupt by setting MSR\textsubscript{DE} to 1. Software in the Debug interrupt handler can observe DBSR IDE to determine how to interpret the value in CSRR\textsubscript{0}/DSRR\textsubscript{0}.

### 10.4.2 Data Address Compare Debug Event

One or more Data Address Compare debug events (DAC1R, DAC1W, DAC2R, DAC2W) occur if they are enabled, execution is attempted of a data storage access instruction, and the type, address, and possibly even the data value of the data storage access meet the criteria specified in the Debug Control Register 0, Debug Control Register 2, and the DAC1 and DAC2 Registers.

#### Data Address Compare Read/Write Enable

DBCR\textsubscript{0DAC1} specifies whether DAC1R debug events can occur on read-type data storage accesses and whether DAC1W debug events can occur on write-type data storage accesses.

DBCR\textsubscript{0DAC2} specifies whether DAC2R debug events can occur on read-type data storage accesses and whether DAC2W debug events can occur on write-type data storage accesses.

Indexed-string instructions (\textit{lswx}, \textit{stswx}) for which the XER field specifies zero bytes as the length of the string are treated as no-ops, and are not allowed to cause Data Address Compare debug events.

All Load instructions are considered reads with respect to debug events, while all Store instructions are considered writes with respect to debug events. In addition, the Cache Management instructions, and certain special cases, are handled as follows.

- \textit{dcbt}, \textit{dcbtls}, \textit{dcbilq}, \textit{dcbtep}, \textit{icbt}, \textit{icbtls}, \textit{icbi}, \textit{icblic}, \textit{icbliq}, \textit{dcblc}, and \textit{icbipe} are all considered reads with respect to debug events. Note that \textit{dcbt}, \textit{dcbtep}, and \textit{icbt} are treated as no-operations when they report Data Storage or Data TLB Miss exceptions, instead of being allowed to cause interrupts. However, these instructions are allowed to cause Debug interrupts, even when they would otherwise have been no-op’ed due to a Data Storage or Data TLB Miss exception.

- \textit{dcbtst}, \textit{dcbtstls}, \textit{dcbtstep}, \textit{dcbz}, \textit{dcbzep}, \textit{dcbi}, \textit{dcbf}, \textit{dcbfep}, \textit{dcba}, \textit{dcbst}, and \textit{dcbstep} are all considered writes with respect to debug events. Note that \textit{dcbf}, \textit{dcbfep}, \textit{dcbst}, and \textit{dcbstep} are considered reads with respect to Data Storage exceptions, since they do not actually change the data at a given address. However, since the execution of these instructions may result in write activity on the data bus, they are treated as writes with respect to debug events. Note also that \textit{dcbtst} and \textit{dcbtstep} are treated as no-operations when they report Data Storage or Data TLB Miss exceptions, instead of being allowed to cause interrupts. However, these instructions are allowed to cause Debug interrupts, even when they would otherwise have been no-op’ed due to a Data Storage or Data TLB Miss exception.

#### Data Address Compare User/Supervisor Mode

DBCR\textsubscript{2DAC1US} specifies whether DAC1R and DAC1W debug events can occur in user mode or supervisor mode, or both.

DBCR\textsubscript{2DAC2US} specifies whether DAC2R and DAC2W debug events can occur in user mode or supervisor mode, or both.

#### Effective/Real Address Mode

DBCR\textsubscript{2DAC1ER} specifies whether effective addresses, real addresses, effective addresses and MSR\textsubscript{DS}=0, or effective addresses and MSR\textsubscript{DS}=1 are used to in determining an address match on DAC1R and DAC1W debug events.

DBCR\textsubscript{2DAC2ER} specifies whether effective addresses, real addresses, effective addresses and MSR\textsubscript{DS}=0, or effective addresses and MSR\textsubscript{DS}=1 are used to in determining an address match on DAC2R and DAC2W debug events.

#### Data Address Compare Mode

DBCR\textsubscript{2DAC12M} specifies whether all or some of the bits of the address of the data storage access must match the contents of the DAC1 or DAC2, whether the address must be inside a specific range specified by the DAC1 and DAC2 or outside a specific range specified by the DAC1 and DAC2 for a DAC1R, DAC1W, DAC2R or DAC2W debug event to occur.

There are four data address compare modes.

- **Exact address compare mode**
  
  If the 64-bit address of the data storage access is equal to the value in the enabled Data Address Compare Register, a data address match occurs.

Chapter 10. Debug Facilities 1217
For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

- **Address bit match mode**
  If the address of the data storage access, ANDed with the contents of the DAC2, are equal to the contents of the DAC1, also ANDed with the contents of the DAC2, a data address match occurs.

For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

- **Inclusive address range compare mode**
  If the 64-bit address of the data storage access is greater than or equal to the contents of the DAC1 and less than the contents of the DAC2, a data address match occurs.

For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

- **Exclusive address range compare mode**
  If the 64-bit address of the data storage access is less than the contents of the DAC1 or greater than or equal to the contents of the DAC2, a data address match occurs.

For 64-bit implementations, the addresses are masked to compare only bits 32:63 when the thread is executing in 32-bit mode.

The description of DBCR0 (see Section 10.5.1.1) and DBCR2 (see Section 10.5.1.3) and the modes for detecting Data Address Compare debug events. Data Address Compare debug events can occur regardless of the setting of MSRDE or DBCR0IDM.

When an Data Address Compare debug event occurs, the corresponding DBSRDAC1R, DBSRDAC1W, DBSRDAC2R, or DBSRDAC2W bit or bits are set to 1 to record the debug exception. If MSRDE=0, DBSRIDE is also set to 1 to record the imprecise debug event.

If MSRDE=1 (i.e. Debug interrupts are enabled) at the time of the Data Address Compare debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), the execution of the instruction causing the exception will be suppressed, and CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will contain the address of the instruction after the one which enabled the Debug interrupt by setting MSRDE to 1. Software in the Debug interrupt handler can observe DBSRIDE to determine how to interpret the value in CSRR0/DSRR0 [Category: Embedded.Enhanced Debug].

Later, if the debug exception has not been reset by clearing DBSRDAC1R, DBSRDAC1W, DBSRDAC2R, DBSRDAC2W, and MSRDE is set to 1, a delayed Debug interrupt will occur. In this case, CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will be set to the address of the exceptioning instruction.

If MSRDE=1 (i.e. Debug interrupts are enabled) at the time of the Trap debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), and CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will be set to the address of the exceptioning instruction.

If MSRDE=0 (i.e. Debug interrupts are disabled) at the time of the Trap debug exception, a Debug interrupt will not occur, and a Trap exception type Program interrupt will occur instead if the trap condition is met. Later, if the debug exception has not been reset by clearing DBSRTR, and MSRDE is set to 1, a delayed Debug interrupt will occur. In this case, CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will contain the address of the instruction after the one which enabled the Debug interrupt by setting both MSRDE and DBCR0IDM to 1. Software in the Debug interrupt handler can observe DBSRIDE to determine how to interpret the value in CSRR0/DSRR0 [Category: Embedded.Enhanced Debug].

### 10.4.3 Trap Debug Event

A Trap debug event (TRAP) occurs if DBCR0TRAP=1 (i.e. Trap debug events are enabled) and a Trap instruction (tw, twi, td, tdi) is executed and the conditions specified by the instruction for the trap are met. The event can occur regardless of the setting of MSRDE or DBCR0IDM.

When a Trap debug event occurs, DBSRTR is set to 1 to record the debug exception. If MSRDE=0, DBSRIDE is also set to 1 to record the imprecise debug event.

If MSRDE=1 (i.e. Debug interrupts are enabled) at the time of the Trap debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), and CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will be set to the address of the exceptioning instruction.

If MSRDE=0 (i.e. Debug interrupts are disabled) at the time of the Trap debug exception, a Debug interrupt will not occur, and a Trap exception type Program interrupt will occur instead if the trap condition is met.

### 10.4.4 Branch Taken Debug Event

A Branch Taken debug event (BRT) occurs if DBCR0BRT=1 (i.e. Branch Taken Debug events are enabled), execution is attempted of a branch instruction whose direction will be taken (that is, either an unconditional branch, or a conditional branch whose branch condition is met), and MSRDE=1.
Branch Taken debug events are not recognized if MSR$_{DE}$=0 at the time of the execution of the branch instruction and thus DBSR$_{IDE}$ can not be set by a Branch Taken debug event. This is because branch instructions occur very frequently. Allowing these common events to be recorded as exceptions in the DBSR while debug interrupts are disabled via MSR$_{DE}$ would result in an inordinate number of imprecise Debug interrupts.

When a Branch Taken debug event occurs, the DBSR$_{BRT}$ bit is set to 1 to record the debug exception and a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt). The execution of the instruction causing the exception will be suppressed, and CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will be set to the address of the excepting instruction.

### 10.4.5 Instruction Complete Debug Event

An Instruction Complete debug event (ICMP) occurs if DBCR$_0$ICMP=1 (i.e. Instruction Complete debug events are enabled), execution of any instruction is completed, and MSR$_{DE}$=1. Note that if execution of an instruction is suppressed due to the instruction causing some other exception which is enabled to generate an interrupt, then the attempted execution of that instruction does not cause an Instruction Complete debug event. The sc instruction does not fall into the type of an instruction whose execution is suppressed, since the instruction actually completes execution and then generates a System Call interrupt. In this case, the Instruction Complete debug exception will also be set.

Instruction Complete debug events are not recognized if MSR$_{DE}$=0 at the time of the execution of the instruction, DBSR$_{IDE}$ can not be set by an ICMP debug event. This is because allowing the common event of Instruction Completion to be recorded as an exception in the DBSR while Debug interrupts are disabled via MSR$_{DE}$ would mean that the Debug interrupt handler software would receive an inordinate number of imprecise Debug interrupts every time Debug interrupts were re-enabled via MSR$_{DE}$.

When an Instruction Complete debug event occurs, DBSR$_{ICMP}$ is set to 1 to record the debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), and CSRR0/DSRR0 [Category: Embedded.Enhanced Debug] will be set to the address of the instruction after the one causing the Instruction Complete debug exception.

### 10.4.6 Interrupt Taken Debug Event

#### 10.4.6.1 Causes of Interrupt Taken Debug Events

Only base class interrupts and guest class interrupts (Category: Embedded.Hypervisor) can cause an Interrupt Taken debug event. If the Embedded.Enhanced Debug category is not supported or is supported and not enabled, all other interrupts automatically clear MSR$_{DE}$, and thus would always prevent the associated Debug interrupt from occurring precisely. If the Embedded.Enhanced Debug category is supported and enabled, then critical class interrupts do not automatically clear MSR$_{DE}$, but they cause Critical Interrupt Taken debug events instead of Interrupt Taken debug events.

Also, if the Embedded.Enhanced Debug category is not supported or is supported and not enabled, Debug interrupts themselves are critical class interrupts, and thus any Debug interrupt (for any other debug event) would always end up setting the additional exception of DBSR$_{IRPT}$ upon entry to the Debug interrupt handler. At this point, the Debug interrupt handler would be unable to determine whether or not the Interrupt Taken debug event was related to the original debug event.

#### 10.4.6.2 Interrupt Taken Debug Event Description

An Interrupt Taken debug event (IRPT) occurs if DBCR$_0$IRPT=1 (i.e. Interrupt Taken debug events are enabled) and a base class interrupt occurs. Interrupt Taken debug events can occur regardless of the setting of MSR$_{DE}$.

When an Interrupt Taken debug event occurs, DBSR$_{IRPT}$ is set to 1 to record the debug exception. If MSR$_{DE}$=0, DBSR$_{IDE}$ is also set to 1 to record the imprecise debug event.

If MSR$_{DE}$=1 (i.e. Debug interrupts are enabled) at the time of the Interrupt Taken debug event, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), and Critical Save/Restore Register 0/Debug Save/Restore Register 0 [Category: Embedded.Enhanced Debug] will be set to the address of the interrupt vector which caused the Interrupt Taken debug event. No instructions at the base interrupt handler will have been executed.

If MSR$_{DE}$=0 (i.e. Debug interrupts are disabled) at the time of the Interrupt Taken debug event, a Debug interrupt will not occur, and the handler for the interrupt which caused the Interrupt Taken debug event will be allowed to execute.
Later, if the debug exception has not been reset by clearing DBSR\_UDE, and MSR\_DE is set to 1, a delayed Debug interrupt will occur. In this case, CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug] will contain the address of the instruction after the one which enabled the Debug interrupt by setting MSR\_DE to 1. Software in the Debug interrupt handler can observe the DBSR\_IDE bit to determine how to interpret the value in CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug].

### 10.4.7 Return Debug Event

A Return debug event (RET) occurs if DBCR\_RET = 1 and an attempt is made to execute an rfi (and also rfgi <E.HV>). Return debug events can occur regardless of the setting of MSR\_DE.

When a Return debug event occurs, DBSR\_RET is set to 1 to record the debug exception. If MSR\_DE = 0, DBSR\_IDE is also set to 1 to record the imprecise debug event.

If MSR\_DE = 1 at the time of the Return Debug event, a Debug interrupt will occur immediately, and CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug] will be set to the address of the rfi.

If MSR\_DE = 0 at the time of the Return Debug event, a Debug interrupt will not occur.

Later, if the debug exception has not been reset by clearing DBSR\_RET, and MSR\_DE is set to 1, a delayed imprecise Debug interrupt will occur. In this case, CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug] will contain the address of the instruction after the one which enabled the Debug interrupt by setting MSR\_DE to 1. An imprecise Debug interrupt can be caused by executing an rfi when DBCR\_RET = 1 and MSR\_DE = 0, and the execution of that rfi happens to cause MSR\_DE to be set to 1. Software in the Debug interrupt handler can observe the DBSR\_IDE bit to determine how to interpret the value in CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug].

### 10.4.8 Unconditional Debug Event

An Unconditional debug event (UDE) occurs when the Unconditional Debug Event (UDE) signal is activated by the debug mechanism. The exact definition of the UDE signal and how it is activated is implementation-dependent. The Unconditional debug event is the only debug event which does not have a corresponding enable bit for the event in DBCR\_UDE (hence the name of the event). The Unconditional debug event can occur regardless of the setting of MSR\_DE.

When an Unconditional debug event occurs, the DBSR\_UDE bit is set to 1 to record the Debug exception. If MSR\_DE = 0, DBSR\_IDE is also set to 1 to record the imprecise debug event.

If MSR\_DE = 1 (i.e. Debug interrupts are enabled) at the time of the Unconditional Debug exception, a Debug interrupt will occur immediately (provided there exists no higher priority exception which is enabled to cause an interrupt), and CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug] will contain the address of the instruction after the one which enabled the Debug interrupt by setting MSR\_DE to 1. Software in the Debug interrupt handler can observe DBSR\_IDE to determine how to interpret the value in CSR\_R0/DSR\_R0 [Category: Embedded.Enhanced Debug].

### 10.4.9 Critical Interrupt Taken Debug Event

A Critical Interrupt Taken debug event (CIRPT) occurs if DBCR\_CIRPT = 1 (i.e. Critical Interrupt Taken debug events are enabled) and a critical interrupt occurs. A critical interrupt is any interrupt that saves state in CSR\_R0 and CSR\_R1 when the interrupt is taken. Critical Interrupt Taken debug events can occur regardless of the setting of MSR\_DE.

When a Critical Interrupt Taken debug event occurs, DBSR\_CIRPT is set to 1 to record the debug event. If MSR\_DE = 0, DBSR\_IDE is also set to 1 to record the imprecise debug event.

If MSR\_DE = 1 (i.e. Debug Interrupts are enabled) at the time of the Critical Interrupt Taken debug event, a Debug Interrupt will occur immediately (provided there is no higher priority exception which is enabled to cause an interrupt), and DSRR\_R0 will contain the address of the first instruction of the critical interrupt handler. No instructions at the critical interrupt handler will have been executed.

If MSR\_DE = 0 (i.e. Debug Interrupts are disabled) at the time of the Critical Interrupt Taken debug event, a Debug Interrupt will not occur, and the handler for the critical interrupt which caused the debug event will be allowed to execute normally. Later, if the debug exception has not been reset by clearing DBSR\_CIRPT and MSR\_DE is set to 1, a delayed Debug Interrupt will occur. In this case DSRR\_R0 will contain the address of the instruction after the one that set MSR\_DE = 1. Software in the Debug Interrupt handler can observe DBSR\_IDE to determine how to interpret the value in DSRR\_R0.
10.4.10 Critical Interrupt Return Debug Event [Category: Embedded Enhanced Debug]

A Critical Interrupt Return debug event (CRET) occurs if DBCR0CRET = 1 (i.e. Critical Interrupt Return debug events are enabled) and an attempt is made to execute an rfci instruction. Critical Interrupt Return debug events can occur regardless of the setting of MSRDE.

When a Critical Interrupt Return debug event occurs, DBSRCRET is set to 1 to record the debug event. If MSRDE=0, DBSRIDE is also set to 1 to record the imprecise debug event.

If MSRDE = 1 (i.e. Debug Interrupts are enabled) at the time of the Critical Interrupt Return debug event, a Debug Interrupt will occur immediately (provided there is no higher priority exception which is enabled to cause an interrupt), and DSRR0 will be set to the address of the rfci instruction.

If MSRDE = 0 (i.e. Debug Interrupts are disabled) at the time of the Critical Interrupt Return debug event, a Debug Interrupt will not occur. Later, if the debug exception has not been reset by clearing DBSRCRET and MSRDE is set to 1, a delayed Debug Interrupt will occur. In this case DSRR0 will contain the address of the instruction after the one that set MSRDE = 1. An imprecise Debug Interrupt can be caused by executing an rfci when DBCR0CRET = 1 and MSRDE = 0, and the execution of the rfci happens to cause MSRDE to be set to 1. Software in the Debug Interrupt handler can observe DBSRIDE to determine how to interpret the value in DSRR0.

10.5 Debug Registers

This section describes debug-related registers that are accessible to software. These registers are intended for use by special debug tools and debug software, and not by general application or operating system code.

10.5.1 Debug Control Registers

Debug Control Register 0 (DBCR0), Debug Control Register 1 (DBCR1), and Debug Control Register 2 (DBCR2) are each 32-bit registers. Bits of DBCR0, DBCR1, and DBCR2 are numbered 32 (most-significant bit) to 63 (least-significant bit). DBCR0, DBCR1, and DBCR2 are used to enable debug events, reset the thread, control timer operation during debug events, and set the debug mode of the thread.

10.5.1.1 Debug Control Register 0 (DBCR0)

The contents of the DBCR0 can be read into bits 32:63 of register RT using mfspr RT, DBCR0, setting bits 0:31 of RT to 0. The contents of bits 32:63 of register RS can be written to the DBCR0 using mt spr DBCR0, RS. The bit definitions for DBCR0 are shown below.

</tbody>
</table>
**Note:** Taken branches will not cause a BRT debug event if MSR<sub>DE</sub>=0.

38 **Interrupt Taken Debug Event Enable** (IRPT)

- 0 IRPT debug events are disabled
- 1 IRPT debug events are enabled

**Note:** Critical interrupts will not cause an IRPT Debug event even if MSR<sub>DE</sub>=0. If the Embedded.Enhanced Debug category is supported, see Section 10.4.9.

39 **Trap Debug Event Enable** (TRAP)

- 0 TRAP debug events cannot occur
- 1 TRAP debug events can occur

40 **Instruction Address Compare 1 Debug Event Enable** (IAC1)

- 0 IAC1 debug events cannot occur
- 1 IAC1 debug events can occur

41 **Instruction Address Compare 2 Debug Event Enable** (IAC2)

- 0 IAC2 debug events cannot occur
- 1 IAC2 debug events can occur

42 **Instruction Address Compare 3 Debug Event Enable** (IAC3)

- 0 IAC3 debug events cannot occur
- 1 IAC3 debug events can occur

43 **Instruction Address Compare 4 Debug Event Enable** (IAC4)

- 0 IAC4 debug events cannot occur
- 1 IAC4 debug events can occur

44:45 **Data Address Compare 1 Debug Event Enable** (DAC1)

- 00 DAC1 debug events cannot occur
- 01 DAC1 debug events can occur only if a store-type data storage access
- 10 DAC1 debug events can occur only if a load-type data storage access
- 11 DAC1 debug events can occur on any data storage access

46:47 **Data Address Compare 2 Debug Event Enable** (DAC2)

- 00 DAC2 debug events cannot occur
- 01 DAC2 debug events can occur only if a store-type data storage access
- 10 DAC2 debug events can occur only if a load-type data storage access
- 11 DAC2 debug events can occur on any data storage access

48 **Return Debug Event Enable** (RET)

- 0 RET debug events cannot occur
- 1 RET debug events can occur

**Note:** Return From Critical Interrupt will not cause an RET debug event if MSR<sub>DE</sub>=0. If the Embedded.Enhanced Debug category is supported, see Section 10.4.10

49:56 Reserved

57 **Critical Interrupt Taken Debug Event** (CIRPT) [Category: Embedded.Enhanced Debug]

A Critical Interrupt Taken Debug Event occurs when DBCR0<sub>CIRPT</sub> = 1 and a critical interrupt (any interrupt that uses the critical class, i.e. uses CSRR0 and CSRR1) occurs.

- 0 Critical interrupt taken debug events are disabled.
- 1 Critical interrupt taken debug events are enabled.

58 **Critical Interrupt Return Debug Event** (CRET) [Category: Embedded.Enhanced Debug]

A Critical Interrupt Return Debug Event occurs when DBCR0<sub>CRET</sub> = 1 and a return from critical interrupt (an rfc<sub>i</sub> instruction is executed) occurs.

- 0 Critical interrupt return debug events are disabled.
- 1 Critical interrupt return debug events are enabled.

59:62 Implementation-dependent

63 **Freeze Timers on Debug Event** (FT)

- 0 Enable clocking of timers and Time Base
- 1 Disable clocking of timers and Time Base if any DBSR bit is set (except MRR)

**Virtualized Implementation Note**

The FT bit may not be supported in virtualized implementations.

This register is hypervisor privileged.

10.5.1.2 Debug Control Register 1 (DBCR1)

The contents of the DBCR1 can be read into bits 32:63 a register RT using **mtspr** RT, DBCR1, setting bits 0:31 of RT to 0. The contents of bits 32:63 of register RS can be written to the DBCR1 using **mtspr** DBCR1, RS. The bit definitions for DBCR1 are shown below.

**Bit(s) Description**

32:33 **Instruction Address Compare 1 User/ Supervisor Mode** (IAC1US)

- 00 IAC1 debug events can occur
- 01 Reserved
10 IAC1 debug events can occur only if MSRPR=0
11 IAC1 debug events can occur only if MSRPR=1

34:35 Instruction Address Compare 1 Effective/Real Mode (IAC1ER)
00 IAC1 debug events are based on effective addresses
01 IAC1 debug events are based on real addresses
10 IAC1 debug events are based on effective addresses and can occur only if MSRS=0
11 IAC1 debug events are based on effective addresses and can occur only if MSRS=1

36:37 Instruction Address Compare 2 User/Supervisor Mode (IAC2US)
00 IAC2 debug events can occur
01 Reserved
10 IAC2 debug events can occur only if MSRPR=0
11 IAC2 debug events can occur only if MSRPR=1

38:39 Instruction Address Compare 2 Effective/Real Mode (IAC2ER)
00 IAC2 debug events are based on effective addresses
01 IAC2 debug events are based on real addresses
10 IAC2 debug events are based on effective addresses and can occur only if MSRS=0
11 IAC2 debug events are based on effective addresses and can occur only if MSRS=1

40:41 Instruction Address Compare 1/2 Mode (IAC12M)
00 Exact address compare
IAC1 debug events can occur only if the address of the instruction fetch is equal to the value specified in IAC1.
IAC2 debug events can occur only if the address of the instruction fetch is equal to the value specified in IAC2.

01 Address bit match
IAC1 and IAC2 debug events can occur only if the address of the instruction fetch, ANDed with the contents of IAC2 are equal to the contents of IAC1, also ANDed with the contents of IAC2.
If IAC1US≠IAC2US or IAC1ER≠IAC2ER, results are boundedly undefined.

10 Inclusive address range compare
IAC1 and IAC2 debug events can occur only if the address of the instruction fetch is greater than or equal to the value specified in IAC1 and less than the value specified in IAC2.
If IAC1US≠IAC2US or IAC1ER≠IAC2ER, results are boundedly undefined.

11 Exclusive address range compare
IAC1 and IAC2 debug events can occur only if the address of the instruction fetch is less than the value specified in IAC1 or is greater than or equal to the value specified in IAC2.
If IAC1US≠IAC2US or IAC1ER≠IAC2ER, results are boundedly undefined.

42:47 Reserved

48:49 Instruction Address Compare 3 User/Supervisor Mode (IAC3US)
00 IAC3 debug events can occur

00 IAC4 debug events are based on effective addresses
01 IAC4 debug events are based on real addresses
10 IAC4 debug events are based on effective addresses and can occur only if MSRS=0
11 IAC4 debug events are based on effective addresses and can occur only if MSRS=1
56:57 Instruction Address Compare 3/4 Mode (IAC34M)

00 Exact address compare
IAC3 debug events can occur only if the address of the instruction fetch is equal to the value specified in IAC3.
IAC4 debug events can occur only if the address of the instruction fetch is equal to the value specified in IAC4.

01 Address bit match
IAC3 and IAC4 debug events can occur only if the address of the data storage access, ANDed with the contents of IAC4 are equal to the contents of IAC3, also ANDed with the contents of IAC4.
If IAC3US≠IAC4US or IAC3ER≠IAC4ER, results are boundedly undefined.

10 Inclusive address range compare
IAC3 and IAC4 debug events can occur only if the address of the instruction fetch is greater than or equal to the value specified in IAC3 and less than the value specified in IAC4.
If IAC3US≠IAC4US or IAC3ER≠IAC4ER, results are boundedly undefined.

11 Exclusive address range compare
IAC3 and IAC4 debug events can occur only if the address of the instruction fetch is less than the value specified in IAC3 or is greater than or equal to the value specified in IAC4.
If IAC3US≠IAC4US or IAC3ER≠IAC4ER, results are boundedly undefined.

58:63 Reserved
This register is hypervisor privileged.

10.5.1.3 Debug Control Register 2 (DBCR2)
The contents of the DBCR2 can be copied into bits 32:63 register RT using mfspr RT,DBCR2, setting bits 0:31 of register RT to 0. The contents of bits 32:63 of a register RS can be written to the DBCR2 using mtspr DBCR2,RS. The bit definitions for DBCR2 are shown below.

Bit(s) Description
32:33 Data Address Compare 1 User/Supervisor Mode (DAC1US)

00 DAC1 debug events can occur
01 Reserved
10 DAC1 debug events can occur only if MSRPR=0
11 DAC1 debug events can occur only if MSRPR=1

34:35 Data Address Compare 1 Effective/Real Mode (DAC1ER)

00 DAC1 debug events are based on effective addresses
01 DAC1 debug events are based on real addresses
10 DAC1 debug events are based on effective addresses and can occur only if MSRDS=0
11 DAC1 debug events are based on effective addresses and can occur only if MSRDS=1

36:37 Data Address Compare 2 User/Supervisor Mode (DAC2US)

00 DAC2 debug events can occur
01 Reserved
10 DAC2 debug events can occur only if MSRPR=0
11 DAC2 debug events can occur only if MSRPR=1

38:39 Data Address Compare 2 Effective/Real Mode (DAC2ER)

00 DAC2 debug events are based on effective addresses
01 DAC2 debug events are based on real addresses
10 DAC2 debug events are based on effective addresses and can occur only if MSRDS=0
11 DAC2 debug events are based on effective addresses and can occur only if MSRDS=1

40:41 Data Address Compare 1/2 Mode (DAC12M)

00 Exact address compare

Architecture Note

For IAC12M inclusive (10) and exclusive (11) range comparisons, either DBCR0IAC1 or DBCR0IAC2 can be set to one in order to enable the range comparison. It is permissible for both DBCR0IAC1 and DBCR0IAC2 to be enabled. In that case, both DBSR1IAC1 and DBSR1IAC2 will be set for a range match.
The same behavior holds for IAC34M with the appropriate substitutions.
DAC1 debug events can occur only if the address of the data storage access is equal to the value specified in DAC1.

DAC2 debug events can occur only if the address of the data storage access is equal to the value specified in DAC2.

01 Address bit match

DAC1 and DAC2 debug events can occur only if the address of the data storage access, ANDed with the contents of DAC2 are equal to the contents of DAC1, also ANDed with the contents of DAC2.

If DAC1US ≠ DAC2US or DAC1ER ≠ DAC2ER, results are boundedly undefined.

10 Inclusive address range compare

DAC1 and DAC2 debug events can occur only if the address of the data storage access is greater than or equal to the value specified in DAC1 and less than the value specified in DAC2.

If DAC1US ≠ DAC2US or DAC1ER ≠ DAC2ER, results are boundedly undefined.

11 Exclusive address range compare

DAC1 and DAC2 debug events can occur only if the address of the data storage access is less than the value specified in DAC1 or is greater than or equal to the value specified in DAC2.

If DAC1US ≠ DAC2US or DAC1ER ≠ DAC2ER, results are boundedly undefined.

42:63 Reserved

Architecture Note

Bits 44:63 will be among the last to be assigned a meaning as these bits contained the DVC (Data Value Compare) function in earlier versions of the architecture.

This register is hypervisor privileged.

Architecture Note

For DAC12M inclusive (10) and exclusive (11) range comparisons, either DBCR0DAC1 or DBCR0DAC2 can be set to one in order to enable the range comparison. It is permissible for both DBCR0DAC1 and DBCR0DAC2 to be enabled. In that case, both DBSRDAC1 and DBSRDAC2 will be set for a range match.

The same behavior holds for DAC34M with the appropriate substitutions.

10.5.2 Debug Status Register

The Debug Status Register (DBSR) is a 32-bit register and contains status on debug events and the most recent thread reset.

The DBSR is set via hardware, and read and cleared via software. The contents of the DBSR can be read into bits 32:63 of a register RT using the\texttt{mfspr} instruction, setting bits 0:31 of RT to zero. Bits in the DBSR can be cleared using the\texttt{mtspr} instruction. Clearing is done by writing bits 32:63 of a register to the DBSR with a 1 in any bit position that is to be cleared and 0 in all other bit positions. The write-data to the DBSR is not direct data, but a mask. A 1 causes the bit to be cleared, and a 0 has no effect.

The bit definitions for the DBSR are shown below:

<table>
<thead>
<tr>
<th>Bit(s)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>Imprecise Debug Event (IDE)</td>
</tr>
<tr>

</tr>
<tr>
<td>39</td>
<td>Trap Instruction Debug Event (TRAP)</td>
</tr>
</tbody>
</table>

Set to 1 if a Trap Instruction debug event occurred and DBCR0\text{TRAP}=1. See Section 10.4.3.

**Instruction Address Compare 1 Debug Event** (IAC1)
Set to 1 if an IAC1 debug event occurred and DBCR0\text{IAC1}=1. See Section 10.4.1.

**Instruction Address Compare 2 Debug Event** (IAC2)
Set to 1 if an IAC2 debug event occurred and DBCR0\text{IAC2}=1. See Section 10.4.1.

**Instruction Address Compare 3 Debug Event** (IAC3)
Set to 1 if an IAC3 debug event occurred and DBCR0\text{IAC3}=1. See Section 10.4.1.

**Instruction Address Compare 4 Debug Event** (IAC4)
Set to 1 if an IAC4 debug event occurred and DBCR0\text{IAC4}=1. See Section 10.4.1.

**Data Address Compare 1 Read Debug Event** (DAC1R)
Set to 1 if a read-type DAC1 debug event occurred and DBCR0\text{DAC1}=0b10 or DBCR0\text{DAC1}=0b11. See Section 10.4.2.

**Data Address Compare 1 Write Debug Event** (DAC1W)
Set to 1 if a write-type DAC1 debug event occurred and DBCR0\text{DAC1}=0b01 or DBCR0\text{DAC1}=0b11. See Section 10.4.2.

**Data Address Compare 2 Read Debug Event** (DAC2R)
Set to 1 if a read-type DAC2 debug event occurred and DBCR0\text{DAC2}=0b10 or DBCR0\text{DAC2}=0b11. See Section 10.4.2.

**Data Address Compare 2 Write Debug Event** (DAC2W)
Set to 1 if a write-type DAC2 debug event occurred and DBCR0\text{DAC2}=0b01 or DBCR0\text{DAC2}=0b11. See Section 10.4.2.

**Return Debug Event** (RET)
Set to 1 if a Return debug event occurred and DBCR0\text{RET}=1. See Section 10.4.2.

0 Critical interrupt taken debug events are disabled.
1 Critical interrupt taken debug events are enabled.

**Critical Interrupt Return Debug Event** (CRET) [Category: Embedded.Enhanced Debug]
A Critical Interrupt Return Debug Event occurs when DBCR0CRET=1 and a return from critical interrupt (an \textit{rfci} instruction is executed) occurs.

0 Critical interrupt return debug events are disabled.
1 Critical interrupt return debug events are enabled.

Implementation-dependent
This register is hypervisor privileged.
10.5.3 Debug Status Register Write Register (DBSRWR)

The Debug Status Register Write Register (DBSRWR) allows a hypervisor state program to write the contents of the Debug Status Register (see Section 10.5.2, “Debug Status Register”). The format of the DBSRWR is shown in Figure 86 below.

![DBSRWR Diagram](image)

Figure 86. Debug Status Register Write Register

The DBSRWR is provided as a means to restore the contents of the DBSR on a partition switch.

The DBSRWR is hypervisor privileged.

Writing DBSRWR changes the value in the DBSR. Writing non-zero bits may enable an imprecise Debug exception which may cause later imprecise Debug Interrupts. In order to correctly write DBSRWR, software should ensure that MSRDE = 0 when the value is written and perform a context synchronizing operation before setting MSRDE to 1.

10.5.4 Instruction Address Compare Registers

The Instruction Address Compare Register 1, 2, 3, and 4 (IAC1, IAC2, IAC3, and IAC4 respectively) are each 64-bits, with bit 63 being reserved.

A debug event may be enabled to occur upon an attempt to execute an instruction from an address specified in either IAC1, IAC2, IAC3, or IAC4, inside or outside a range specified by IAC1 and IAC2 or, inside or outside a range specified by IAC3 and IAC4, or to blocks of addresses specified by the combination of the IAC1 and IAC2, or to blocks of addresses specified by the combination of the IAC3 and IAC4. Since all instruction addresses are required to be word-aligned, the two low-order bits of the Instruction Address Compare Registers are reserved and do not participate in the comparison to the instruction address (see Section 10.4.1 on page 1215).

The contents of the Instruction Address Compare i Register (where $i = \{1, 2, 3, \text{ or } 4\}$) can be read into register RT using $\text{mfspr RT, IAC}i$. The contents of register RS can be written to the Instruction Address Compare i Register using $\text{mtspr IAC}i, RS$.

This register is hypervisor privileged.

10.5.5 Data Address Compare Registers

The Data Address Compare Register 1 and 2 (DAC1 and DAC2 respectively) are each 64-bits.

A debug event may be enabled to occur upon loads, stores, or cache operations to an address specified in either the DAC1 or DAC2, inside or outside a range specified by the DAC1 and DAC2, or to blocks of addresses specified by the combination of the DAC1 and DAC2 (see Section 10.4.2).

The contents of the Data Address Compare i Register (where $i = \{1 \text{ or } 2\}$) can be read into register RT using $\text{mfspr RT, DAC}i$. The contents of register RS can be written to the Data Address Compare i Register using $\text{mtspr DAC}i, RS$.

The contents of the DAC1 or DAC2 are compared to the address generated by a data storage access instruction.

These registers are hypervisor privileged.
10.6 Debugger Notify Halt Instruction

The *dnh* instruction provides the means for the transfer of information between the thread and an implementation-dependent external debug facility. *dnh* also causes the thread to stop fetching and executing instructions.

**Debugger Notify Halt**  
**XFX-form**

\[
\text{dnh \ DUI,DUIS}
\]

if enabled by implementation-dependent means
then
  \[
  \text{implementation-dependent register} \leftarrow \text{DUI}
  \]
  halt thread
else
  illegal instruction exception

Execution of the *dnh* instruction causes the thread to stop fetching instructions and taking interrupts if execution of the instruction has been enabled. The contents of the DUI field are sent to the external debug facility to identify the reason for the halt.

If execution of the *dnh* instruction has not been previously enabled, executing the *dnh* instruction produces an Illegal Instruction exception. The means by which execution of the *dnh* instruction is enabled is implementation-dependent.

The current state of the debug facility, whether the thread is in IDM or EDM mode has no effect on the execution of the *dnh* instruction.

The instruction is context synchronizing.

**Programming Note**

The DUI field in the instruction may be used to pass information to an external debug facility. After the *dnh* instruction has executed, the instruction itself can be read back by the Illegal Instruction Interrupt handler or the external debug facility if the contents of the DUI field are of interest. If the thread entered the Illegal Instruction Interrupt handler, software can use SRR0 to obtain the address of the *dnh* instruction which caused the handler to be invoked.

**Special Registers Altered:**

None
Chapter 11. Processor Control [Category: Embedded.Processor Control]

11.1 Overview

The Processor Control facility provides a mechanism for threads within a coherence domain to send messages to all devices in the coherence domain. The facility provides a mechanism for sending interrupts that are not dependent on the interrupt controller to threads and allows message filtering by the threads that receive the message.

The Processor Control facility is also useful for sending messages to a device that provides specialized services such as secure boot operations controlled by a security device.

The Processor Control facility defines how threads send messages and what actions threads take on the receipt of a message. The actions taken by devices other than threads are not defined.

Programming Note

A common use of `msgsnd` is to deliver an external interrupt to a partition which has set MSR_{EE}=0. A guest doorbell message will interrupt to the hypervisor when MSR_{EE}=1 and MSR_{GS}=1. The hypervisor can then deliver the external interrupt to the partition. For Servers, a similar set of operations can also be performed using the Book III-S `msgsnd` instruction. These operations achieve a result analogous to the mediated external interrupt in Book III-S.

11.2 Programming Model

Threads initiate a message by executing the `msgsnd` instruction and specifying a message type and message payload in a general purpose register. Sending a message causes the message to be sent to all the devices, including the sending thread, in the coherence domain in a reliable manner.

Each device receives all messages that are sent. The actions that a device takes are dependent on the message type and payload. There are no restrictions on what messages a thread can send.

To provide inter thread interrupt capability the following do<e:hi>rbell</e:hi> message types are defined:

- Processor Doorbell
- Processor Doorbell Critical
- Guest Processor Doorbell <E.HV>
- Guest Processor Doorbell Critical <E.HV>
- Guest Processor Doorbell Machine Check <E.HV>

A doorbell message causes an interrupt to occur on threads when the message is received and the thread determines through examination of the payload that the message should be accepted. The examination of the payload for this purpose is termed filtering. The acceptance of a doorbell message causes an exception to be generated on the accepting thread.

Threads accept and filter messages defined in Section 11.2.1. Threads may also accept other implementation-dependent defined messages.

11.2.1 Message Handling and Filtering

Threads filter, accept, and handle message types defined as follows. The message type is specified in the message and is determined by the contents of register RB_{32:36} used as the operand in the `msgsnd` instruction. The message type is interpreted as follows:

<table>
<thead>
<tr>
<th>Value</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td><strong>Doorbell Interrupt</strong> (DBELL)</td>
</tr>
<tr>
<td></td>
<td>A Processor Doorbell exception is generated on the thread when the thread has filtered the message based on the payload and has determined that it should accept the message. A Processor Doorbell Interrupt occurs when no higher priority exception exists, a Processor Doorbell exception exists, and the interrupt is enabled (MSR_{EE}=1). If Category: Embedded.Hypervisor is supported, the interrupt is enabled if (MSR_{EE}=1 or MSR_{GS}=1).</td>
</tr>
</tbody>
</table>
1. **Doorbell Critical Interrupt** (DBELL_CRIT)  
A Processor Doorbell Critical exception is generated on the thread when the thread has filtered the message based on the payload and has determined that it should accept the message. A Processor Doorbell Critical Interrupt occurs when no higher priority exception exists, a Processor Doorbell Critical exception exists, and the interrupt is enabled (MSR\text{CE}=1). If Category: Embedded.Hypervisor is supported, the interrupt is enabled if (MSR\text{CE}=1 or MSR\text{GS}=1).

2. **Guest Doorbell Interrupt** (G_DBELL) 
   
   A Guest Processor Doorbell exception is generated on the thread when the thread has filtered the message based on the payload and has determined that it should accept the message. A Guest Processor Doorbell Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell exception exists, and the interrupt is enabled (MSR\text{EE}=1 and MSR\text{GS}=1).

3. **Guest Doorbell Interrupt Critical** (G_DBELL_CRIT) 
   
   A Guest Processor Doorbell Critical exception is generated on the thread when the thread has filtered the message based on the payload and has determined that it should accept the message. A Guest Processor Doorbell Critical Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell Critical exception exists, and the interrupt is enabled (MSR\text{CE}=1 and MSR\text{GS}=1).

4. **Guest Doorbell Interrupt Machine Check** (G_DBELL_MC) 
   
   A Guest Processor Doorbell Machine Check exception is generated on the thread when the thread has filtered the message based on the payload and has determined that it should accept the message. A Guest Processor Doorbell Machine Check Interrupt occurs when no higher priority exception exists, a Guest Processor Doorbell Machine Check exception exists, and the interrupt is enabled (MSR\text{ME}=1 and MSR\text{GS}=1).

Message types other than these and their associated actions are implementation-dependent.

**11.2.2 Doorbell Message Filtering**

A thread receiving a DBELL message will filter the message and either ignore the message or accept the message and generate a Processor Doorbell exception based on the payload and the state of the thread at the time the message is received.

The payload is specified in the message and is determined by the contents of register RB\text{37:63} used as the operand in the `msgsnd` instruction. The payload bits are defined below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Broadcast (BRDCAST)</td>
</tr>
<tr>
<td></td>
<td>If set, the message is accepted by all threads regardless of the value of the PIR register and the value of PIRTAG.</td>
</tr>
<tr>
<td></td>
<td>0 If the value of PIR and PIRTAG are equal a Processor Doorbell exception is generated.</td>
</tr>
<tr>
<td></td>
<td>1 A Processor Doorbell exception is generated regardless of the value of PIRTAG and PIR.</td>
</tr>
<tr>
<td>38:49</td>
<td>LPID Tag (LPIDTAG)</td>
</tr>
<tr>
<td></td>
<td>The contents of this field are compared with the contents of the LPIDR. If LPIDTAG = 0, it matches all values in the LPIDR register.</td>
</tr>
<tr>
<td>50:63</td>
<td>PIR Tag (PIRTAG)</td>
</tr>
<tr>
<td></td>
<td>The contents of this field are compared with bits 50:63 of the PIR register.</td>
</tr>
</tbody>
</table>

If category E.HV is supported by the thread on which a DBELL message is received, the message will only be accepted if it is for this partition (payload\text{LPIDTAG} = LPIDR) or it is for all partitions (payload\text{LPIDTAG} = 0) and it meets the additional criteria for acceptance below.

If a DBELL message is received by a thread, the message is accepted and a Processor Doorbell exception is generated if one of the following conditions exist:

- This is a broadcast message (payload\text{BRDCAST}=1);
- The message is intended for this thread (PIR\text{50:63}=payload\text{PIRTAG});

The exception condition remains until a Processor Doorbell Interrupt is taken, or a `msgclr` instruction is executed on the receiving thread with a message type of DBELL. A change to any of the filtering criteria (i.e. changing the PIR register) will not clear a pending Processor Doorbell exception.

DBELL messages are not cumulative. That is, if a DBELL message is accepted and the interrupt is pended because MSR\text{EE}=0, additional DBELL messages that would be accepted are ignored until the Processor Doorbell exception is cleared by taking the interrupt or cleared by executing a `msgclr` with a message type of DBELL on the receiving thread.

The temporal relationship between when a DBELL message is sent and when it is received in a given thread is not defined.

**11.2.2.1 Doorbell Critical Message Filtering**

A thread receiving a DBELL_CRIT message type will filter the message and either ignore the message or
accept the message and generate a Processor Doorbell Critical exception based on the payload and the state of the thread at the time the message is received.

The payload is specified in the message and is determined by the contents of register RB\textsubscript{37:63} used as the operand in the \texttt{msgsnd} instruction. The payload bits are defined below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Broadcast (BRDCAST)</td>
</tr>
<tr>
<td>38:49</td>
<td>\texttt{LPID Tag} (LPIDTAG)</td>
</tr>
<tr>
<td>50:63</td>
<td>\texttt{PIR Tag} (PIRTAG)</td>
</tr>
</tbody>
</table>

If category E.HV is supported by the thread on which a DBELL\_CRIT message is received, the message will only be accepted if it is for this partition (payload\textsubscript{LPIDTAG} = LPIDR) or it is for all partitions (payload\textsubscript{LPIDTAG} = 0) and it meets the additional criteria for acceptance below.

If a DBELL\_CRIT message is received by a thread, the message is accepted and a Processor Doorbell Critical exception is generated if one of the following conditions exist:

- This is a broadcast message (payload\textsubscript{BRDCAST}=1);
- The message is intended for this thread (PIR\textsubscript{50:63}=payload\textsubscript{PIRTAG}).

DBELL\_CRIT messages are not cumulative. That is, if a DBELL\_CRIT message is accepted and the interrupt is pended because MSR\textsubscript{CE}=0, additional DBELL\_CRIT messages that would be accepted are ignored until the Processor Doorbell Critical exception is cleared by taking the interrupt or cleared by executing a \texttt{msgclr} with a message type of DBELL\_CRIT on the receiving thread.

The temporal relationship between when a DBELL\_CRIT message is sent and when it is received in a given thread is not defined.

The temporal relationship between when a DBELL\_CRIT message is sent and when it is received in a given thread is not defined.

11.2.2.2 Guest Doorbell Message Filtering [Category: Embedded.Hypervisor]

A thread receiving a G\_DBELL message type will filter the message and either ignore the message or accept the message and generate a Guest Processor Doorbell Critical exception based on the payload and the state of the thread at the time the message is received.

The payload is specified in the message and is determined by the contents of register RB\textsubscript{37:63} used as the operand in the \texttt{msgsnd} instruction. The payload bits are defined below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Broadcast (BRDCAST)</td>
</tr>
<tr>
<td>38:49</td>
<td>\texttt{LPID Tag} (LPIDTAG)</td>
</tr>
<tr>
<td>50:63</td>
<td>\texttt{PIR Tag} (PIRTAG)</td>
</tr>
</tbody>
</table>

When a G\_DBELL message is received by a thread, the message will only be accepted if it is for this partition (payload\textsubscript{LPIDTAG} = LPIDR) or it is for all partitions (payload\textsubscript{LPIDTAG} = 0) and it meets the additional criteria for acceptance below.

The message is accepted and a Guest Processor Doorbell exception is generated if one of the following conditions exist:

- This is a broadcast message (payload\textsubscript{BRDCAST}=1);
- The message is intended for this thread (GPIR\textsubscript{50:63}=payload\textsubscript{PIRTAG}).

G\_DBELL messages are not cumulative. That is, if a G\_DBELL message is accepted and the interrupt is pended because MSR\textsubscript{CE}=0, additional G\_DBELL messages that would be accepted are ignored until the Guest Processor Doorbell exception is cleared by taking the interrupt or cleared by executing a \texttt{msgclr} with a message type of G\_DBELL on the receiving thread.

The temporal relationship between when a G\_DBELL message is sent and when it is received in a given thread is not defined.

The temporal relationship between when a G\_DBELL message is sent and when it is received in a given thread is not defined.
11.2.2.3 Guest Doorbell Critical Message Filtering [Category: Embedded.Hypervisor]

A thread receiving a G_DBELL_CRIT message type will filter the message and either ignore the message or accept the message and generate a Guest Processor Doorbell Critical exception based on the payload and the state of the thread at the time the message is received.

The payload is specified in the message and is determined by the contents of register RB\textsubscript{37:63} used as the operand in the \texttt{msgsnd} instruction. The payload bits are defined below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Broadcast (BRDCAST)</td>
</tr>
<tr>
<td>0</td>
<td>If the value of GPIR and PIRTAG are equal a Guest Processor Doorbell Critical exception is generated.</td>
</tr>
<tr>
<td>1</td>
<td>A Guest Processor Doorbell Critical exception is generated regardless of the value of PIRTAG and GPIR.</td>
</tr>
<tr>
<td>38:49</td>
<td>LPID Tag (LPIDTAG)</td>
</tr>
<tr>
<td>50:63</td>
<td>PIR Tag (PIRTAG)</td>
</tr>
</tbody>
</table>

When a G_DBELL_CRIT message is received by a thread, the message will only be accepted if it is for this partition (payload\textsubscript{LPIDTAG} = LPIDR) or it is for all partitions (payload\textsubscript{LPIDTAG} = 0) and it meets the additional criteria for acceptance below.

If a G_DBELL_CRIT message is received by a thread, the message is accepted and a Guest Processor Doorbell Critical exception is generated if one of the following conditions exist:
- This is a broadcast message (payload\textsubscript{BRDCAST}=1);
- The message is intended for this thread (GPIR\textsubscript{50:63}=payload\textsubscript{PIRTAG});

G_DBELL_CRIT messages are not cumulative. That is, if a G_DBELL_CRIT message is accepted and the interrupt is pended because MSR\textsubscript{CE}=0, additional G_DBELL messages that would be accepted are ignored until the Guest Processor Doorbell Critical exception is cleared by taking the interrupt or cleared by executing a \texttt{msgclr} with a message type of G_DBELL_CRIT on the receiving thread.

The temporal relationship between when a G_DBELL_CRIT message is sent and when it is received in a given thread is not defined.

11.2.2.4 Guest Doorbell Machine Check Message Filtering [Category: Embedded.Hypervisor]

A thread receiving a G_DBELL_MC message type will filter the message and either ignore the message or accept the message and generate a Guest Processor Doorbell Machine Check exception based on the payload and the state of the thread at the time the message is received.

The payload is specified in the message and is determined by the contents of register RB\textsubscript{37:63} used as the operand in the \texttt{msgsnd} instruction. The payload bits are defined below.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Broadcast (BRDCAST)</td>
</tr>
<tr>
<td>0</td>
<td>If the value of GPIR and PIRTAG are equal a Guest Processor Doorbell Machine Check exception is generated.</td>
</tr>
<tr>
<td>1</td>
<td>A Guest Processor Doorbell Machine Check exception is generated regardless of the value of PIRTAG and GPIR.</td>
</tr>
<tr>
<td>38:49</td>
<td>LPID Tag (LPIDTAG)</td>
</tr>
<tr>
<td>50:63</td>
<td>PIR Tag (PIRTAG)</td>
</tr>
</tbody>
</table>

When a G_DBELL_MC message is received by a thread, the message will only be accepted if it is for this partition (payload\textsubscript{LPIDTAG} = LPIDR) or it is for all partitions (payload\textsubscript{LPIDTAG} = 0) and it meets the additional criteria for acceptance below.

If a G_DBELL_MC message is received by a thread, the message is accepted and a Guest Processor Doorbell Machine Check exception is generated if one of the following conditions exist:
- This is a broadcast message (payload\textsubscript{BRDCAST}=1);
- The message is intended for this thread (GPIR\textsubscript{50:63}=payload\textsubscript{PIRTAG});

G_DBELL_MC messages are not cumulative. That is, if a G_DBELL_MC message is accepted and the interrupt is pended because MSR\textsubscript{CE}=0, additional G_DBELL_MC messages that would be accepted are ignored until the Guest Processor Doorbell Machine Check exception is cleared by taking the interrupt or cleared by executing a \texttt{msgclr} with a message type of G_DBELL_MC on the receiving thread.

The temporal relationship between when a G_DBELL_MC message is sent and when it is received in a given thread is not defined.
## 11.3 Processor Control Instructions

`msgsnd` and `msgclr` instructions are provided for sending and clearing messages to threads and other devices in the coherence domain. These instructions are hypervisor privileged.

### Message Send

* `msgsnd` RB

<table>
<thead>
<tr>
<th>msgtype</th>
<th>RB</th>
<th>payload</th>
</tr>
</thead>
<tbody>
<tr>
<td>GPR(RB)32:36</td>
<td>GPR(RB)37:63</td>
<td></td>
</tr>
</tbody>
</table>

`msgsnd` sends a message to all devices in the coherence domain. The message contains a type and a payload. The message type (`msgtype`) is defined by the contents of RB32:36 and the message payload is defined by the contents of RB37:63. Message delivery is reliable and guaranteed. Each device may perform specific actions based on the message type and payload or may ignore messages. Consult implementation documentation for specific actions taken based on message type and payload.

For threads, actions taken on receipt of a message are defined in Section 11.2.1.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

### Programming Note

If `msgsnd` is used to send a message notifying the receiver that updates have been made to storage, a `sync` instruction should be placed between the stores and the `msgsnd`. See Section 6.11.3, “Synchronize Instruction” on page 1124.

### Message Clear

* `msgclr` RB

<table>
<thead>
<tr>
<th>msgtype</th>
<th>RB</th>
<th>payload</th>
</tr>
</thead>
<tbody>
<tr>
<td>GPR(RB)32:36</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

`msgclr` clears a message of `msgtype` previously accepted by the thread executing the `msgclr`. `msgtype` is defined by the contents of RB32:36. A message is said to be cleared when the associated interrupt is masked.

A context synchronizing instruction or event that is executed or occurs subsequent to the execution of `msgclr` ensures that the formerly pending exception will not result in an interrupt when the corresponding interrupt class is reenabled.

For threads, the types of messages that can be cleared are defined in Section 11.2.1.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

### Programming Note

Execution of a `msgclr` instruction that clears a pending exception when the associated interrupt is masked because the interrupt enable (MSR_{EE} or MSR_{CE}) is set to 0 will always clear the pending exception (and thus the interrupt will not occur) only if the instruction that sets MSR_{EE} or MSR_{CE} to 1 is context synchronizing or a context synchronizing operation occurs subsequent to the instruction but before MSR_{EE} or MSR_{CE} is set to 1.
Chapter 12. Synchronization Requirements for Context Alterations

Changing the contents of certain System Registers, the contents of TLB entries, or the contents of other system resources that control the context in which a program executes can have the side effect of altering the context in which data addresses and instruction addresses are interpreted, and in which instructions are executed and data accesses are performed. For example, changing certain bits in the MSR has the side effect of changing how instruction addresses are calculated. These side effects need not occur in program order, and therefore may require explicit synchronization by software. (Program order is defined in Book II.)

An instruction that alters the context in which data addresses or instruction addresses are interpreted, or in which instructions are executed or data accesses are performed, is called a context-altering instruction. This chapter covers all the context-altering instructions. The software synchronization required for them is shown in Table 13 (for data access) and Table 12 (for instruction fetch and execution).

The notation “CSI” in the tables means any context synchronizing instruction (e.g., sc, isync, rfi, rfci, rfmci, or rfdi [Category: Embedded. Enhanced Debug]). A context synchronizing interrupt (i.e., any interrupt except non-recoverable Machine Check) can be used instead of a context synchronizing instruction. If it is, phrases like “the synchronizing instruction”, below, should be interpreted as meaning the instruction at which the interrupt occurs. If no software synchronization is required before (after) a context-altering instruction, “the synchronizing instruction before (after) the context-altering instruction” should be interpreted as meaning the context-altering instruction itself.

The synchronizing instruction before the context-altering instruction ensures that all instructions up to and including that synchronizing instruction are fetched and executed in the context that existed before the alteration. The synchronizing instruction after the context-altering instruction ensures that all instructions after that synchronizing instruction are fetched and executed in the context established by the alteration. Instructions after the first synchronizing instruction, up to and including the second synchronizing instruction, may be fetched or executed in either context.

If a sequence of instructions contains context-altering instructions and contains no instructions that are affected by any of the context alterations, no software synchronization is required within the sequence.

Programming Note

Sometimes advantage can be taken of the fact that certain events, such as interrupts, and certain instructions that occur naturally in the program, such as an rfi, rfgi [Category: Embedded.Hypervisor], rfci, rfmci, or rfdi [Category: Embedded. Enhanced Debug] that returns from an interrupt handler, provide the required synchronization.

No software synchronization is required before or after a context-altering instruction that is also context synchronizing (e.g., rfi, etc.) or when altering the MSR in most cases (see the tables). No software synchronization is required before most of the other alterations shown in Table 12, because all instructions preceding the context-altering instruction are fetched and decoded before the context-altering instruction is executed (the hardware must determine whether any of these preceding instructions are context synchronizing).

Unless otherwise stated, the material in this chapter assumes a single-threaded environment.
Notes:

1. There are additional software synchronization requirements for this instruction in multi-threaded environments (e.g., it may be necessary to invalidate one or more TLB entries on all threads in the system and to be able to determine that the invalidations have completed and that all side effects of the invalidations have taken effect); it is also necessary to execute a `tlbsync` instruction.

2. The alteration must not cause an implicit branch in real address space. Thus the real address of the context-altering instruction and of each subsequent instruction, up to and including the next context synchronizing instruction, must be

Notes:

1. There are additional software synchronization requirements for this instruction in multi-threaded environments (e.g., it may be necessary to invalidate one or more TLB entries on all threads in the system and to be able to determine that the invalidations have completed and that all side effects of the invalidations have taken effect); it is also necessary to execute a `tlbsync` instruction.

2. The alteration must not cause an implicit branch in real address space. Thus the real address of the context-altering instruction and of each subsequent instruction, up to and including the next context synchronizing instruction, must be
independent of whether the alteration has taken effect.

3. A context synchronizing instruction is required after altering MSRME to ensure that the alteration takes effect for subsequent Machine Check interrupts, which may not be recoverable and therefore may not be context synchronizing.

4. The effect of changing MSR_EE or MSR_CE is immediate.

If an mtmsr, wrtee, or wrteei instruction sets MSR_EE to '0', an External Input, DEC or FIT interrupt does not occur after the instruction is executed.

If an mtmsr, wrtee, or wrteei instruction changes MSR_EE from '0' to '1' when an External Input, Decrementer, Fixed-Interval Timer, or higher priority enabled exception exists, the corresponding interrupt occurs immediately after the mtmsr, wrtee, or wrteei is executed, and before the next instruction is executed in the program that set MSR_EE to '1'.

If an mtmsr instruction sets MSR_CE to '0', a Critical Input or Watchdog Timer interrupt does not occur after the instruction is executed.

If an mtmsr instruction changes MSR_CE from '0' to '1' when a Critical Input or Watchdog Timer interrupt occurs immediately after the mtmsr is executed, and before the next instruction is executed in the program that set MSR_CE to '1'.

5. Synchronization requirements for changing any of the Debug Facility Registers are implementation-dependent.

6. For data accesses, the context synchronizing instruction before the tlbwe, tlblix, or tlbivax instruction ensures that all storage accesses due to preceding instructions have completed to a point at which they have reported all exceptions they will cause.

The context synchronizing instruction after the tlbwe, tlblix, or tlbivax ensures that subsequent storage accesses (data and instruction) will use the updated value in the TLB entry(s) being affected. It does not ensure that all storage accesses previously translated by the TLB entry(s) being updated have completed with respect to storage; if these completions must be assured, the tlbwe, tlblix, or tlbivax must be followed by a sync instruction as well as by a context synchronizing instruction.

7. The elapsed time between the Decrementer reaching zero, or the transition of the selected Time Base bit for the Fixed-Interval Timer or the Watchdog Timer, and the signalling of the Decrementer, Fixed-Interval Timer or the Watchdog Timer exception is not defined.

8. The notation "(sync, CSI)" denotes an instruction sequence. Other instructions may be interleaved with this sequence, but these instructions must appear in the order shown.

Programming Note

The following sequence illustrates why it is necessary, for data accesses, to ensure that all storage accesses due to instructions before the tlbwe or tlbivax have completed to a point at which they have reported all exceptions they will cause. Assume that valid TLB entries exist for the target storage location when the sequence starts.

- A program issues a load or store to a page.
- The same program executes a tlbwe or tlbivax that invalidates the corresponding TLB entry.
- The Load or Store instruction finally executes, and gets a TLB Miss exception.
- The TLB Miss exception is semantically incorrect. In order to prevent it, a context synchronizing instruction must be executed between steps 1 and 2.

No software synchronization is required before the Store instruction because (a) stores are not performed out-of-order and (b) address translations associated with instructions preceding the Store instruction are not performed again after the store has been performed (see Section 5.5). These properties ensure that all address translations associated with instructions preceding the Store instruction will be performed using the old contents of the PTE.

The sync instruction after the Store instruction ensures that all lookups of the Page Table that are performed after the sync instruction completes will use the value stored (or a value stored subsequently). The context synchronizing instruction after the sync instruction ensures that any address translations associated with instructions following the context synchronizing instruction that were performed using the old contents of the PTE will be discarded, with the result that these address translations will be performed again and, if there is no corresponding entry in any implementation-specific address translation lookaside information, will use the value stored (or a value stored subsequently).
The `sync` instruction also ensures that all storage accesses associated with instructions preceding the `sync` instruction, before the `sync` instruction is executed, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required or Alternate Coherence Mode attributes, before any data accesses caused by instructions following the `sync` instruction are performed with respect to that thread or mechanism.

9. After executing a `mtspr` that sets one of the TLB invalidate all bits in the MMUCSR0 to a 1, software must read MMUCSR0 using a `mfspr` instruction until the corresponding bit is zero and then perform the CSI, or CSI and `sync` as indicated in the “Required After” column.
Appendix A. Implementation-Dependent Instructions

This appendix documents architectural resources that are allocated for specific implementation-sensitive functions which have scope-limited utility. Implementations may exercise reasonable flexibility in implementing these functions, but that flexibility should be limited to that allowed in this appendix.

A.1 Embedded Cache Initialization [Category: Embedded.Cache Initialization]

**Data Cache Invalidate**

<table>
<thead>

<td>16</td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

If CT is not supported by the implementation, this instruction designates the primary data cache as the target data cache.

If CT is supported by the implementation, let CT designate either the primary data cache or another level of the data cache hierarchy, as specified in Section 4.3, “Cache Management Instructions”, in Book II, as the target data cache.

The contents of the target data cache of the thread executing the dci instruction are invalidated.

Software must place a sync instruction before the dci to guarantee all previous data storage accesses complete before the dci is performed.

Software must place a sync instruction after the dci to guarantee that the dci completes before any subsequent data storage accesses are performed.

This instruction is hypervisor privileged.

If CT is not supported by the implementation, this instruction designates the primary instruction cache as the target instruction cache.

If CT is supported by the implementation, let CT designate either the primary instruction cache or another level of the instruction cache hierarchy, as specified in Section 4.3, “Cache Management Instructions”, in Book II, as the target instruction cache.

The contents of the target instruction cache of the thread executing the ici instruction are invalidated.

Software must place a sync instruction before the ici to guarantee all previous instruction storage accesses complete before the ici is performed.

Software must place an isync instruction after the ici to invalidate any instructions that may have already been fetched from the previous contents of the instruction cache after the isync.

This instruction is hypervisor privileged.

A.2.2 Embedded Cache Debug Instructions

**Data Cache Read X-form**

```plaintext
dcread RT,RA,RB
```

<table>
<thead>
<tr>
<th>0</th>
<th>31</th>
<th>RT</th>
<th>6</th>
<th>RA</th>
<th>11</th>
<th>RB</th>
<th>16</th>
<th>326</th>
<th>21</th>
<th>486</th>
</tr>
</thead>
</table>

[Alternative Encoding]

```plaintext
if RA = 0 then b ← 0
else
    b ← (RA)
EA ← b + (RB)
C ← log₂(cache size)
B ← log₂(cache block size)
IDX ← EA₆₄⁻₄₈⁻₃₂⁻₁₆⁻₈⁻₄⁻₂⁻₁⁻₀
WD ← EA₆₄⁻₄₈⁻₃₂⁻₂₄⁻₁₆⁻₈⁻₄⁻₂⁻₁⁻₀
RT₀⁻₃₁ ← undefined
RT₃₂⁻₆₃ ← (data cache data)[IDX]₉₋₆₃₋₆₁
DCDBTRH ← (data cache tag high)[IDX]
DCDBTRL ← (data cache tag low)[IDX]
```

Let the effective address (EA) be the sum of the contents of register RA, or 0 if RA is equal to 0, and the contents of register RB.

Let C = log₂(cache size in bytes).
Let B = log₂(cache block size in bytes).

EA₆₄⁻₄₈⁻₃₂⁻₁₆⁻₈⁻₄⁻₂⁻₁⁻₀ selects one of the 2ᶜ⁻ᵇ data cache blocks.

EA₆₄⁻₄₈⁻₃₂⁻₂₄⁻₁₆⁻₈⁻₄⁻₂⁻₁⁻₀ selects one of the data words in the selected data cache block.

The selected word in the selected data cache block is placed into register RT.

The contents of the data cache directory entry associated with the selected data cache block are placed into DCDBTRH and DCDBTRL (see Figure 87 and Figure 88).

*dcread* requires software to guarantee execution synchronization before subsequent *mfspr* instructions can read the results of the *dcread* instruction into GPRs. In order to guarantee that the *mfspr* instructions obtain the results of the *dcread* instruction, a sequence such as the following must be used:

```plaintext
sync # ensure that all previous cache operations have completed
dcread regT,regA,regB# read cache information;
isync # ensure dcread completes before attempting to read results
mfspr regD,dcdbtrh # move high portion of tag into GPR D
mfspr regE,dcdbtrl # move low portion of tag into GPR E
```

This instruction is hypervisor privileged.

**Special Registers Altered:**

```
DCDBTRH DCDBTRL
```

---

**Programming Note**

*dcread* can be used by a debug tool to determine the contents of the data cache, without knowing the specific addresses of the blocks which are currently contained within the cache.

---

**Programming Note**

Execution of *dcread* before the data cache has completed all cache operations associated with previously executed instructions (such as block fills and block flushes) is undefined.
**Instruction Cache Read X-form**

**icread** RA, RB

<table>
<thead>
<tr>
<th>31</th>
<th>6</th>
<th>11</th>
<th>16</th>
<th>21</th>
<th>998</th>
</tr>
</thead>
</table>

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + (RB)
C ← \(\log_2(\text{cache size})\)
B ← \(\log_2(\text{cache block size})\)
IDX ← \(EA_{64-C:63-B}\)
WD ← \(EA_{64-B:61}\)
ICDBDR ← \(\text{(instruction cache data)[IDX]}\)
ICDBTRH ← \(\text{(instruction cache tag high)[IDX]}\)
ICDBTRL ← \(\text{(instruction cache tag low)[IDX]}\)

Let the effective address (EA) be the sum of the contents of register RA, or 0 if RA is equal to 0, and the contents of register RB.

Let C = \(\log_2(\text{cache size in bytes})\).
Let B = \(\log_2(\text{cache block size in bytes})\).

\(EA_{64-C:63-B}\) selects one of the \(2^{C-B}\) instruction cache blocks.

\(EA_{64-B:61}\) selects one of the data words in the selected instruction cache block.

The selected word in the selected instruction cache block is placed into ICDBDR.

The contents of the instruction cache directory entry associated with the selected cache block are placed into ICDBTRH and ICDBTRL (see Figure 90 and Figure 91).

**icread** requires software to guarantee execution synchronization before subsequent **mfspr** instructions can read the results of the **icread** instruction into GPRs. In order to guarantee that the **mfspr** instructions obtain the results of the **icread** instruction, a sequence such as the following must be used:

```
icread   regA, regB  # read cache information
isync     # ensure icread completes
          # before attempting to
          # read results
mficdbdr  regC  # move instruction
          # information into GPR C
mficdbtrh regD  # move high portion of
          # tag into GPR D
mficdbtrl regE  # move low portion of tag
          # into GPR E
```

This instruction is hypervisor privileged.

**Special Registers Altered:**

ICDBDR  ICDBTRH  ICDBTRL

---

**Programming Note**

**icread** can be used by a debug tool to determine the contents of the instruction cache, without knowing the specific addresses of the blocks which are currently contained within the cache.
Appendix B. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided for certain instructions. This appendix defines extended mnemonics and symbols related to instructions defined in Book III.

Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.
B.1 Move To/From Special Purpose Register Mnemonics

This section defines extended mnemonics for the \texttt{mtspr} and \texttt{mfspr} instructions, including the Special Purpose Registers (SPRs) defined in Book I and certain privileged SPRs, and for the \textit{Move From Time Base} instruction defined in Book II.

The \texttt{mtspr} and \texttt{mfspr} instructions specify an SPR as a numeric operand; extended mnemonics are provided that represent the SPR in the mnemonic rather than requiring it to be coded as an operand. Similar extended mnemonics are provided for the \textit{Move From Time Base} instruction, which specifies the portion of the Time Base as a numeric operand.

Note: \texttt{mftb} serves as both a basic and an extended mnemonic. The Assembler will recognize an \texttt{mftb} mnemonic with two operands as the basic form, and an \texttt{mftb} mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).

\begin{table}[h]
\centering
\begin{tabular}{|l|l|l|l|l|}
\hline
\textbf{Special Purpose Register} & \textbf{Move To SPR} & \textbf{Move From SPR} \\
\hline
\multicolumn{5}{|c|}{\textbf{Extended}} \\
\hline
\textbf{Fixed-Point Exception Register} & \texttt{mtxer Rx} & \texttt{mtspr 1,Rx} & \texttt{mtxer Rx} & \texttt{mfspr Rx,1} \\
\textbf{Link Register} & \texttt{mtlr Rx} & \texttt{mtspr 8,Rx} & \texttt{mtlr Rx} & \texttt{mfspr Rx,8} \\
\textbf{Count Register} & \texttt{mtctr Rx} & \texttt{mtspr 9,Rx} & \texttt{mtctr Rx} & \texttt{mfspr Rx,9} \\
\textbf{Decrementer} & \texttt{mddec Rx} & \texttt{mtspr 22,Rx} & \texttt{mddec Rx} & \texttt{mfspr Rx,22} \\
\textbf{Save/Restore Register 0} & \texttt{mtsr0 Rx} & \texttt{mtspr 26,Rx} & \texttt{mtsr0 Rx} & \texttt{mfspr Rx,26} \\
\textbf{Save/Restore Register 1} & \texttt{mtsr1 Rx} & \texttt{mtspr 27,Rx} & \texttt{mtsr1 Rx} & \texttt{mfspr Rx,27} \\
\textbf{Special Purpose Registers G0 through G3} & \texttt{mtsprg n,Rx} & \texttt{mtspr 272+n,Rx} & \texttt{mtsprg Rx,n} & \texttt{mfspr Rx,272+n} \\
\textbf{Time Base [Lower]} & \texttt{mttbl Rx} & \texttt{mtspr 284,Rx} & \texttt{mftb Rx} & \texttt{mftb Rx,268$^1$} \\
\textbf{Time Base Upper} & \texttt{mtbpu Rx} & \texttt{mtspr 285,Rx} & \texttt{mftb Rx} & \texttt{mftb Rx,269$^1$} \\
\textbf{PPR32} & \texttt{mtprr32 Rx} & \texttt{mtspr 898, Rx} & \texttt{mftpr32 Rx} & \texttt{mfspr Rx,898} \\
\textbf{Processor Version Register} & - & - & \texttt{mpvpr Rx} & \texttt{mfspr Rx,287} \\
\hline
\end{tabular}
\caption{Extended mnemonics for moving to/from an SPR}
\end{table}

$^1$ The \texttt{mftb} instruction is Category: Phased-Out. Assemblers targeting Version 2.03 or later of the architecture should generate an \texttt{mfspr} instruction for the \texttt{mftb} and \texttt{mftbu} extended mnemonics; see the corresponding Assembler Note in the \texttt{mftb} instruction description (see Section 6.2.1 of Book II).
B.2 Data Cache Block Flush
Mnemonics [Category: Embedded.Phased In]

The L field in the Data Cache Block Flush by External PID instruction controls the scope of the flush function performed by the instruction. Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

**Note:** `dcbfep` serves as both a basic and an extended mnemonic. The Assembler will recognize a `dcbfep` mnemonic with three operands as the basic form, and a `dcbflep` mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.

- `dcbfep RA,RB` (equivalent to: `dcbfep RA,RB,0`)
- `dcbflep RA,RB` (equivalent to: `dcbfep RA,RB,1`)
- `dcblfpep RA,RB` (equivalent to: `dcbfep RA,RB,3`
Appendix C. Guidelines for 64-bit Implementations in 32-bit Mode and 32-bit Implementations

C.1 Hardware Guidelines

C.1.1 64-bit Specific Instructions
The instructions in the Category: 64-Bit are considered restricted only to 64-bit processing. A 32-bit implementation need not implement the group; likewise, the 32-bit applications will not utilize any of these instructions. All other instructions shall either be supported directly by the implementation, or sufficient infrastructure will be provided to enable software emulation of the instructions. A 64-bit implementation that is executing in 32-bit mode may choose to take an Unimplemented Instruction Exception when these 64-bit specific instructions are executed.

C.1.2 Registers on 32-bit Implementations
The Power ISA provides 32-bit and 64-bit registers. All 32-bit registers shall be supported as defined in the specification except the MSR and EPCR. The MSR shall be supported as defined in the specification except that CM is treated as a reserved bit. EPCR shall be supported as defined in the specification except that ICM and GICM are treated as reserved bits. Only bits 32:63 of the 64-bit registers are required to be implemented in hardware in a 32-bit implementation except for the 64-bit FPRs. Such 64-bit registers include the LR, the CTR, the XER, the 32 GPRs, SRR0, CSRR0, DSRR0 <E.ED>, MCSRR0, and GSRR0 <E.HV>.

For additional information, see Section 1.5.2 of Book I.

C.1.3 Addressing on 32-bit Implementations
Only bits 32:63 of the 64-bit instruction and data storage effective addresses need to be calculated and presented to main storage. Given that the only branch and data storage access instructions that are not included in Section C.1.1 are defined to prepend 32 0s to bits 32:63 of the effective address computation, a 32-bit implementation can simply bypass the prepending of the 32 0s when implementing these instructions. For Branch to Link Register and Branch to Count Register instructions, given the LR and CTR are implemented only as 32-bit registers, only concatenating 2 0s to the right of bits 32:61 of these registers is necessary to form the 32-bit branch target address.

For next sequential instruction address computation, the behavior is the same as for 64-bit implementations in 32-bit mode.

C.1.4 TLB Fields on 32-bit Implementations
32-bit implementations should support bits 32:53 of the Effective Page Number (EPN) field in the TLB. This size provides support for a 32-bit effective address, which Power ISA ABIs may have come to expect to be available. 32-bit implementations may support greater than 32-bit real addresses by supporting more than bits 32:53 of the Real Page Number (RPN) field in the TLB.

C.1.5 Thread Control and Status on 32-bit Implementations
As the TEN and TENSOR are 32-bits on 32-bit implementations, the maximum number of threads for such implementations is limited to 32.

C.2 32-bit Software Guidelines

C.2.1 32-bit Instruction Selection
Any software that uses any of the instructions listed in Category: 64-Bit shall be considered 64-bit software, and correct execution cannot be guaranteed on 32-bit implementations. Generally speaking, 32-bit software should avoid using any instruction or instructions that depend on any particular setting of bits 0:31 of any 64-bit application-accessible system register, including General Purpose Registers, for producing the correct 32-bit results. Context switching may or may not preserve the upper 32 bits of application-accessible 64-bit
system registers and insertion of arbitrary settings of those upper 32 bits at arbitrary times during the execution of the 32-bit application must not affect the final result.
Appendix D. Example Performance Monitor
[Category: Embedded.Performance Monitor]

D.1 Overview

This appendix describes an example of a Performance Monitor facility. It defines an architecture suitable for performance monitoring facilities in the Embedded environment. The architecture itself presents only programing model visible features in conjunction with architecturally defined behavioral features. Much of the selection of events is by necessity implementation-dependent and is not described as part of the architecture; however, this document provides guidelines for some features of a performance monitor implementation that should be followed by all implementations.

The example Performance Monitor facility provides the ability to monitor and count predefined events such as clocks, misses in the instruction cache or data cache, types of instructions decoded, or mispredicted branches. The count of such events can be used to trigger the Performance Monitor exception. While most of the specific events are not architected, the mechanism of controlling data collection is.

The example Performance Monitor facility can be used to do the following:

- Improve system performance by monitoring software execution and then recoding algorithms for more efficiency. For example, memory hierarchy behavior can be monitored and analyzed to optimize task scheduling or data distribution algorithms.
- Characterize performance in environments not easily characterized by benchmarking.
- Help system developers bring up and debug their systems.

D.2 Programming Model

The example Performance Monitor facility defines a set of Performance Monitor Registers (PMRs) that are used to collect and control performance data collection and an interrupt to allow intervention by software. The PMRs provide various controls and access to collected data. They are categorized as follows:

- Counter registers. These registers are used for data collection. The occurrence of selected events are counted here. These registers are named PMC0..15. User and supervisor level access to these registers is through different PMR numbers allowing different access rights.
- Global controls. This register control global settings of the Performance Monitor facility and affect all counters. This register is named PMGC0. User and supervisor level access to these registers is through different PMR numbers allowing different access rights. In addition, a bit in the MSR (MSRPM) is defined to enable/disable counting.
- Local controls. These registers control settings that apply only to a particular counter. These registers are named PMLCa0..15 and PMLCb0..15. User and supervisor level access to these registers is through different PMR numbers allowing different access rights. Each set of local control registers (PMLCa n and PMLCb n) contains controls that apply to the associated same numbered counter register (e.g. PMLCa0 and PMLCb0 contain controls for PMC0 while PMLCa1 and PMLCb1 contain controls for PMC1).

**Assembler Note**

The counter registers, global controls, and local controls have alias names which cause the assembler to use different PMR numbers. The names PMC0...15, PMGC0, PMLCa0...15, and PMLCb0...15 cause the assembler to use the supervisor level PMR number, and the names UPMC0...15, UPMGC0, UPMLCa0...15, and UPMLCb0...15 cause the assembler to use the user-level PMR number.

**Architecture Note**

The two mark values (0 and 1) are equivalent except with respect to interrupts. That is, either mark value can be specified for a given process, and either mark value can control whether the PMCs are incremented, but interrupts always cause the mark value in the MSR to be set to 0.
A given implementation may implement fewer counter registers (and their associated control registers) than are architected. Architected counter and counter control registers that are not implemented behave the same as unarchitected Performance Monitor Registers. PMRs are described in Section D.3.

Software uses the global and local controls to select which events are counted in the counter registers, when such events should be counted, and what action should be taken when a counter overflows. Software can use the collected information to determine performance attributes of a given segment of code, a process, or the entire software system. PMRs can be read by software using the `mfpmr` instruction and PMRs can be written by using the `mtpmr` instruction. Both instructions are described in Section D.4.

Since counters are defined as 32-bit registers, it is possible for the counting of some events to overflow. A Performance Monitor interrupt is provided that can be programmed to occur in the event of a counter overflow. The Performance Monitor interrupt is described in detail in Section D.2.5 and Section D.2.6.

### D.2.1 Event Counting

Event counting can be configured in several different ways. This section describes configurability and specific unconditional counting modes.

### D.2.2 Thread Context Configurability

Counting can be enabled if conditions in the thread state match a software-specified condition. Because a software task scheduler may switch a thread's execution among multiple processes and because statistics on only a particular process may be of interest, a facility is provided to mark a process. The Performance Monitor mark bit, MSR_PMM, is used for this purpose. System software may set this bit to 1 when a marked process is running. This enables statistics to be gathered only during the execution of the marked process. The states of MSR_PR and MSR_PMM together define a state that the thread (supervisor or user) and the process (marked or unmarked) may be in at any time. If this state matches an individual state specified by the PMLCan_FCS, PMLCan_FCU, PMLCan_FCM1, and PMLCan_FCM0 fields in PMLCan (the state for which monitoring is enabled), counting is enabled for PMCn.

Each event, on an implementation basis, may count regardless of the value of MSR_PMM. The counting behavior of each event should be documented in the User's Manual.

The thread states and the settings of the PMLCan_FCS, PMLCan_FCU, PMLCan_FCM1 and PMLCan_FCM0 fields in PMLCan necessary to enable monitoring of each thread state are shown in Figure 92.

</tbody>
</table>

Figure 92. Thread States and PMLCan Bit Settings

Two unconditional counting modes may be specified:

- Counting is unconditionally enabled regardless of the states of MSR_PMM and MSR_PR. This can be accomplished by setting PMLCan_FCS, PMLCan_FCU, PMLCan_FCM1, and PMLCan_FCM0 to 0 for each counter control.
- Counting is unconditionally disabled regardless of the states of MSR_PMM and MSR_PR. This can be accomplished by setting PMGC0FAC to 1 or by setting PMLCan_FCU to 1 for each counter control. Alternatively, this can be accomplished by setting PMLCan_FCM1 to 1 and PMLCan_FCM0 to 1 for each counter control or by setting PMLCan_FCS to 1 and PMLCan_FCU to 1 for each counter control.

---

**Programming Note**

Events may be counted in a fuzzy manner. That is, events may not be counted precisely due to the nature of an implementation. Users of the Performance Monitor facility should be aware that an event may be counted even if it was precisely filtered, though it should not have been. In general such discrepancies are statistically unimportant and users should not assume that counts are explicitly accurate.

### D.2.3 Event Selection

Events to count are determined by placing an implementation defined event value into the PMLCan0..15EVENT field. Which events may be programmed into which counter are implementation specific and should be defined in the User’s Manual. In general, most events may be programmed into any of the implementation available counters. Programming a counter with an event that is not supported for that counter gives boundedly undefined results.
D.2.4 Thresholds

Thresholds are values that must be exceeded for an event to be counted. Threshold values are programmed in the PMLCb0..15.THRESHOLD field. The events which may be thresholded and the units of each event that may be thresholded are implementation-dependent. Programming a threshold value for an event that is not defined to use a threshold gives boundedly undefined results.

D.2.5 Performance Monitor Exception

A Performance Monitor exception occurs when counter overflow detection is enabled and a counter overflows. More specifically, for each counter register \(n\), if \(\text{PMGC0\_RMIE}=1\), \(\text{PMLCn\_CE}=1\), \(\text{PMCR\_OV}=1\), and the performance monitor interrupt is enabled in the MSR (see below), a Performance Monitor exception is said to exist. The Performance Monitor exception condition will cause a Performance Monitor interrupt if the exception is the highest priority exception.

The performance monitor interrupt enabling conditions in the MSR are as follows:

- If category E.HV is implemented, the performance monitor interrupt is enabled if:
  - \(\text{EPCRPMGS}=0\) and \(\text{MSR\_EE}=1\) or \(\text{MSR\_GS}=1\). The interrupt will be directed to the hypervisor state. or if
  - \(\text{EPCRPMGS}=1\) and \(\text{MSR\_EE}=1\) and \(\text{MSR\_GS}=1\). The interrupt will be directed to the guest state.
- If category E.HV is not implemented, the performance monitor interrupt is enabled if \(\text{MSR\_EE}=1\).

The Performance Monitor exception is level sensitive and the exception condition may cease to exist if any of the required conditions fail to be met. Thus it is possible for a counter to overflow and continue counting events until \(\text{PMCR\_OV}\) becomes 0 without taking a Performance Monitor interrupt if the enabling conditions in the MSR are not met during the overflow condition. To avoid this, software should program the counters to freeze if an overflow condition is detected (see Section D.3.4).

D.2.6 Performance Monitor Interrupt

A Performance Monitor interrupt occurs when a Performance Monitor exception exists and no higher priority exception exists. When a Performance Monitor interrupt occurs, SRR0 and SRR1 (GSR0 and GS1 if \(\text{EPCRPMGS}=1\ <\text{E.HV}\)) record the current state of the NIA and the MSR and the MSR is set to handle the interrupt. Instruction execution resumes at an address based on which categories are supported:

- If both Interrupt Fixed Offsets [Category: Embedded.Phased-In] and Embedded.Hypervisor are supported, instruction execution resumes at:
  - address IVPR0:51 || 0x260 when \(\text{EPCRPMGS}=0\). Otherwise, instruction execution resumes at address GIVPR0:47 || 0x260.
  - If Interrupt Fixed Offsets [Category: Embedded.Phased-In] is supported and Embedded.Hypervisor is not supported, instruction execution resumes at address IVPR0:51 || 0x260.
  - If Interrupt Fixed Offsets [Category: Embedded.Phased-In] is not supported and Embedded.Hypervisor is supported, instruction execution resumes at:
    - address IVPR0:51 || IVOR3548:59 || 0b0000. when \(\text{EPCRPMGS}=0\). Otherwise, instruction execution resumes at address GIVPR0:47 || GIVOR3548:59 || 0b0000.
  - If neither Interrupt Fixed Offsets [Category: Embedded.Phased-In] nor Embedded.Hypervisor is supported, instruction execution resumes at address IVPR0:51 || IVOR3548:59 || 0b0000.

The Performance Monitor interrupt is precise and asynchronous.

---

**Programming Note**

When taking a Performance Monitor interrupt software should clear the overflow condition by reading the counter register and setting the counter register to a non-overflow value since the normal return from the interrupt will set MSR\_EE back to 1.

D.3 Performance Monitor Registers

D.3.1 Performance Monitor Global Control Register 0

The Performance Monitor Global Control Register 0 (PMGC0) controls all Performance Monitor counters.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>PMGC0</td>
<td>32-63</td>
</tr>
</tbody>
</table>

Figure 93. [User] Performance Monitor Global Control Register 0

These bits are interpreted as follows:
Freeze All Counters (FAC)
The FAC bit is sticky; that is, once set to 1 it remains set to 1 until it is set to 0 by an `mtpr` instruction.
- 0 The PMCs can be incremented (if enabled by other Performance Monitor control fields).
- 1 The PMCs cannot be incremented.

Performance Monitor Interrupt Enable (PMIE)
- 0 Performance Monitor interrupts are disabled.
- 1 Performance Monitor interrupts are enabled and occur when an enabled condition or event occurs. Enabled conditions and events are described in Section D.2.5.

Freeze Counters on Enabled Condition or Event (FCECE)
Enabled conditions and events are described in Section D.2.5.
- 0 The PMCs can be incremented (if enabled by other Performance Monitor control fields).
- 1 The PMCs can be incremented (if enabled by other Performance Monitor control fields) only until an enabled condition or event occurs. When an enabled condition or event occurs, PMGC0FAC is set to 1. It is the user’s responsibility to set PMGC0FAC to 0.

Freeze Counter in Supervisor State (FCS)
- 0 The PMC is incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRPR is 0.

Freeze Counter in User State (FCU)
- 0 The PMC can be incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRPR is 1.

Freeze Counter while Mark is Set (FCM1)
- 0 The PMC can be incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRPMM is 1.

Freeze Counter while Mark is Cleared (FCM0)
- 0 The PMC can be incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRPMM is 0.

Condition Enable (CE)
- 0 Overflow conditions for PMC cannot occur (PMC cannot cause interrupts, cannot freeze counters)
- 1 Overflow conditions occur when the most-significant-bit of PMC is equal to 1.

It is recommended that CE be set to 0 when counter PMC is selected for chaining; see Section D.5.1.

Freeze Counter in Guest State (FCGS)
- 0 The PMC is incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRGS is 1.

Freeze Counter in Hypervisor State (FCHS)
- 0 The PMC is incremented (if enabled by other Performance Monitor control fields).
- 1 The PMC cannot be incremented if MSRGS is 0 and MSRPR is 0.

Event Selector (EVENT)
Up to 128 events selectable; see Section D.2.3.

Setting is implementation-dependent.
The UPMLCa0..15 registers are aliases to the PMLCa0..15 registers for user mode read only access.

D.3.3 Performance Monitor Local Control B Registers

The Performance Monitor Local Control B Registers 0 through 15 (PMLCb0..15) specify a threshold value and a multiple to apply to a threshold event selected for the corresponding Performance Monitor counter. Threshold capability is implementation counter dependent. Not all events or all counters of an implementation are guaranteed to support thresholds. PMLCb works with the corresponding numbered PMLCa register.

![Figure 95. Performance Monitor Local Control B Register](image)

PMLCb is set to 0 at reset. These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>52:32</td>
<td>Reserved</td>
</tr>
<tr>
<td>51:53</td>
<td>Threshold Multiple (THRESHMUL)</td>
</tr>
<tr>
<td></td>
<td>000: Threshold field is multiplied by 1 (THRESHOLD × 1)</td>
</tr>
<tr>
<td></td>
<td>001: Threshold field is multiplied by 2 (THRESHOLD × 2)</td>
</tr>
<tr>
<td></td>
<td>010: Threshold field is multiplied by 4 (THRESHOLD × 4)</td>
</tr>
<tr>
<td></td>
<td>011: Threshold field is multiplied by 8 (THRESHOLD × 8)</td>
</tr>
<tr>
<td></td>
<td>100: Threshold field is multiplied by 16 (THRESHOLD × 16)</td>
</tr>
<tr>
<td></td>
<td>101: Threshold field is multiplied by 32 (THRESHOLD × 32)</td>
</tr>
<tr>
<td></td>
<td>110: Threshold field is multiplied by 64 (THRESHOLD × 64)</td>
</tr>
<tr>
<td></td>
<td>111: Threshold field is multiplied by 128 (THRESHOLD × 128)</td>
</tr>
<tr>
<td>62:56</td>
<td>Reserved</td>
</tr>
<tr>
<td>61:63</td>
<td>Threshold (THRESHOLD)</td>
</tr>
</tbody>
</table>

By varying the threshold value, software can obtain a profile of the event characteristics subject to thresholding. For example, if PMC1 is configured to count cache misses that last longer than the threshold value, software can measure the distribution of cache miss durations for a given program by monitoring the program repeatedly using a different threshold value each time.

![Programming Note](image)

The UPMLCb0..15 registers are aliases to the PMLCb0..15 registers for user mode read only access.

D.3.4 Performance Monitor Counter Registers

The Performance Monitor Counter Registers (PMC0..15) are 32-bit counters that can be programmed to generate interrupt signals when they overflow. Each counter is enabled to count up to 128 events.

![Figure 96. Performance Monitor Counter Registers](image)

PMCs are set to 0 at reset. These bits are interpreted as follows:

<table>
<thead>
<tr>
<th>Bit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>32</td>
<td>Overflow (OV)</td>
</tr>
<tr>
<td></td>
<td>0 Counter has not reached an overflow state.</td>
</tr>
<tr>
<td></td>
<td>1 Counter has reached an overflow state.</td>
</tr>
<tr>
<td>62:33</td>
<td>Counter Value (CV)</td>
</tr>
<tr>
<td></td>
<td>Indicates the number of occurrences of the specified event.</td>
</tr>
</tbody>
</table>

The minimum value for a counter is 0 (0x0000_0000) and the maximum value is 4,294,967,295 (0xFFFF_FFFF). A counter can increment up to the maximum value and then wraps to the minimum value. A counter enters the overflow state when the high-order bit is set to 1, which normally occurs only when the counter increments from a value below 2,147,483,648 (0x8000_0000) to a value greater than or equal to 2,147,483,648 (0x8000_0000).

Several different actions may occur when an overflow state is reached, depending on the configuration:

- If PMLCa\_CE is 0, no special actions occur on overflow: the counter continues incrementing, and no exception is signaled.
- If PMLCa\_CE and PMG0\_FCECE are 1, all counters are frozen when PMCn overflows.
- If PMLCa\_CE, PMG0\_PMIE, and MSR\_EE are 1, an exception is signaled when PMCn reaches over-
flow. Note that the interrupts are masked by setting MSR_{EE} to 0. An overflow condition may be present while MSR_{EE} is zero, but the interrupt is not taken until MSR_{EE} is set to 1.

If an overflow condition occurs while MSR_{EE} is 0 (the exception is masked), the exception is still signalled once MSR_{EE} is set to 1 if the overflow condition is still present and the configuration has not been changed in the meantime to disable the exception; however, if MSR_{EE} remains 0 until after the counter leaves the overflow state (MSB becomes 0), or if MSR_{EE} remains 0 until after PMLCn_{CE} or PMGC0_{PMIE} are set to 0, the exception does not occur.

**Programming Note**

Loading a PMC with an overflowed value can cause an immediate exception. For example, if PMLCn_{CE}, PMGC0_{PMIE}, and MSR_{EE} are all 1, and an *mtpmr* loads an overflowed value into a PMCn that previously held a non-overflowed value, then an interrupt will be generated before any event counting has occurred.

The following sequence is generally recommended for setting the counter values and configurations.

1. Set PMGC0_{FAC} to 1 to freeze the counters.
2. Perform a series of *mtpmr* operations to initialize counter values and configure the control registers
3. Release the counters by setting PMGC0_{FAC} to 0 with a final *mtpmr*. 
D.4 Performance Monitor Instructions

**Move From Performance Monitor Register**

XFX-form

```
movefrom pmr

rt,pmr
```

**Move To Performance Monitor Register**

XFX-form

```
moveto pmr

rt,pmr
```

n ← pmrn5:9 || pmrn0:4
if length(PMR(n)) = 64 then
 RT ← PMR(n)
else
 RT ← 32:63 || PMR(n)32:63

Let PMRN denote a Performance Monitor Register number and PMR the set of Performance Monitor Registers.

The contents of the designated Performance Monitor Register are placed into register RT.

The list of defined Performance Monitor Registers and their privilege class is provided in Figure 97.

Execution of this instruction specifying a defined and privileged Performance Monitor Register when MSRPR=1 will result in a Privileged Instruction exception.

Category: Embedded.Hypervisor

If MSRPM = 1 and MSRGS = 1, execution of this instruction specifying a defined Performance Monitor Register sets RT to 0.

Execution of this instruction specifying an undefined Performance Monitor Register will either result in an Illegal Instruction exception or will produce an undefined value for register RT.

Special Registers Altered:

Figure 97. Embedded.Performance Monitor PMRs
D.5 Performance Monitor Software Usage Notes

D.5.1 Chaining Counters

An implementation may contain events that are used to "chain" counters together to provide a larger range of event counts. This is accomplished by programming the desired event into one counter and programming another counter with an event that occurs when the first counter transitions from 1 to 0 in the most significant bit.

The counter chaining feature can be used to decrease the processing pollution caused by Performance Monitor interrupts, (things like cache contamination, and pipeline effects), by allowing a higher event count than is possible with a single counter. Chaining two counters together effectively adds 32 bits to a counter register where the first counter's carry-out event acts like a carry-out feeding the second counter. By defining the event of interest to be another PMC's overflow generation, the chained counter increments each time the first counter rolls over to zero. Multiple counters may be chained together.

Because the entire chained value cannot be read in a single instruction, an overflow may occur between counter reads, producing an inaccurate value. A sequence like the following is necessary to read the complete chained value when it spans multiple counters and the counters are not frozen. The example shown is for a two-counter case.

```
loop:
    mfpmr Rx,pmctr1 #load from upper counter
    mfpmr Ry,pmctr0 #load from lower counter
    mfpmr Rz,pmctr1 #load from upper counter
    cmp cr0,0,Rz,Rx #see if 'old' = 'new'
    bc 4,2,loop
        #loop if carry occurred between reads
```

The comparison and loop are necessary to ensure that a consistent set of values has been obtained. The above sequence is not necessary if the counters are frozen.

D.5.2 Thresholding

Threshold event measurement enables the counting of duration and usage events. Assume an example event, dLFB load miss cycles, requires a threshold value. A dLFB load miss cycles event is counted only when the number of cycles spent recovering from the miss is greater than the threshold. If the event is counted on two counters and each counter has an individual threshold, one execution of a performance monitor program can sample two different threshold values. Measuring code performance with multiple concurrent thresholds expedites code profiling significantly.
Book VLE:

Power ISA Operating Environment Architecture -
Variable Length Encoding (VLE) Environment
[Category: Variable Length Encoding]
Chapter 1. Variable Length Encoding Introduction

This chapter describes computation modes, document conventions, a processor overview, instruction formats, storage addressing, and instruction addressing.

1.1 Overview

Variable Length Encoding (VLE) is a code density optimized re-encoding of much of the instruction set defined by Books I, II, and III-E using both 16-bit and 32-bit instruction formats.

VLE offers more efficient binary representations of applications for the Embedded processor spaces where code density plays a major role in affecting overall system cost, and to a somewhat lesser extent, performance.

VLE is a supplement to the instruction set defined by Book I-III and code pages using VLE encoding or non-VLE encoding can be intermingled in a system providing focus on both high performance and code density where most needed.

VLE provides alternative encodings to instructions defined in Books I-III to enable reduced code footprint. This set of alternative encodings is selected on a page basis. A single storage attribute bit selects between standard instruction encodings and VLE instructions for that page of memory.

Instruction encodings in pages marked as VLE are either 16 or 32 bits long, and are aligned on 16-bit boundaries. Because of this, all instruction pages marked as VLE are required to use Big-Endian byte ordering.

The programming model uses the same register set with both instruction set encodings, although some registers are not accessible by VLE instructions using the 16-bit formats and not all condition register (CR) fields are used by Conditional Branch instructions or instructions that access the condition register executing from a VLE instruction page. In addition, immediate fields and displacements differ in size and use, due to the more restrictive encodings imposed by VLE instruction formats.

VLE additional instruction fields are described in Section 1.4.19, “Instruction Fields”.

Other than the requirement of Big-Endian byte ordering for instruction pages and the additional storage attribute to identify whether the instruction page corresponds to a VLE section of code, VLE complies with the memory model, register model, timer facilities, debug facilities, and interrupt/exception model defined in Book I-III and therefore execute in the same environment as non-VLE instructions.

1.2 Documentation Conventions

Book VLE adheres to the documentation conventions defined in Section 1.3 of Book I. Note however that this book defines instructions that apply to the User Instruction Set Architecture, the Virtual Environment Architecture, and the Operating Environment Architecture.

1.2.1 Description of Instruction Operation

The RTL (register transfer language) descriptions in Book VLE conform to the conventions described in Section 1.3.4 of Book I.

1.3 Instruction Mnemonics and Operands

The description of each instruction includes the mnemonic and a formatted list of operands. VLE instruction semantics are either identical or similar to those of other instructions in the architecture. Where the semantics, side-effects, and binary encodings are identical, the standard mnemonics and formats are used. Such unchanged instructions are listed and appropriately referenced, but the instruction definitions are not replicated in this book. Where the semantics are similar but the binary encodings differ, the standard mnemonic is typically preceded with an _e_ to denote a VLE instruction. To distinguish between similar instructions available in both 16- and 32-bit forms under VLE and standard instructions, VLE instructions encoded with 16 bits have an _se_ prefix. The following are examples:
1.4 VLE Instruction Formats

All VLE instructions to be executed are either two or four bytes long and are halfword-aligned in storage. Thus, whenever instruction addresses are presented to the processor (as in Branch instructions), the low-order bit is treated as 0. Similarly, whenever the processor generates an instruction address, the low-order bit is zero.

The format diagrams given below show horizontally all valid combinations of instruction fields. Only those formats that are unique to VLE-defined instructions are included here. Instruction forms that are available in VLE or non-VLE mode are described in Section 1.6 of Book I and are not repeated here.

In some cases an instruction field must contain a particular value. If a field that must contain a particular value does not contain that value, the instruction form is invalid and the results are as described for invalid instruction forms in Book I.

VLE instructions use split field notation as defined in Section 1.6 of Book I.

1.4.19 Instruction Fields

VLE uses instruction fields defined in Section 1.6.28 of Book I as well as VLE-defined instruction fields defined below.

ARX (12:15)
Field used to specify an “alternate” General Purpose Register in the range R8:R23 to be used as a destination.

ARY (8:11)
Field used to specify an “alternate” General Purpose Register in the range R8:R23 to be used as a source.

BD8 (8:15), BD15 (16:30), BD24 (7:30)
Immediate field specifying a signed two's complement branch displacement which is concatenated on the right with 0b0 and sign-extended to 64 bits.

BD15. (Used by 32-bit branch conditional class instructions) A 15-bit signed displacement that is sign-extended and shifted left one bit (concatenated with 0b0) and then added to the current instruction address to form the branch target address.

BD24. (Used by 32-bit branch class instructions) A 24-bit signed displacement that is
sign-extended and shifted left one bit (concatenated with 0b0) and then added to the current instruction address to form the branch target address.

BD8. (Used by 16-bit branch and branch conditional class instructions) An 8-bit signed displacement that is sign-extended and shifted left one bit (concatenated with 0b0) and then added to the current instruction address to form the branch target address.

BI16 (6:7), BI32 (12:15)
Field used to specify one of the Condition Register fields to be used as a condition of a Branch Conditional instruction.

BO16 (5), BO32 (10:11)
Field used to specify whether to branch if the condition is true, false, or to decrement the Count Register and branch if the Count Register is not zero in a Branch Conditional instruction.

BF32 (9:10)
Field used to specify one of the Condition Register fields to be used as a target of a compare instruction.

D8 (24:31)
The D8 field is a 8-bit signed displacement which is sign-extended to 64 bits.

ELEV (16:20)
Field used by the e_sc instruction.

F (21) Fill value used to fill the remaining 56 bits of a scaled-immediate 8 value.

LI20 (17:20 || 11:15 || 21:31)
A 20-bit signed immediate value which is sign-extended to 64 bits for the e_li instruction.

LK (7, 15, 31)
LINK bit.
0 Do not set the Link Register.
1 Set the Link Register. The sum of the value 2 or 4 and the address of the Branch instruction is placed into the Link Register.

OIM5 (7:11)
Offset Immediate field used to specify a 5-bit unsigned fixed-point value in the range [1:32] encoded as [0:31]. Thus the binary encoding of 0b00000 represents an immediate value of 1, 0b00001 represents an immediate value of 2, and so on.

OPCD (0:3, 0:4, 0:5, 0:9, 0:14, 0:15)
Primary opcode field.

Rc (6, 7, 20, 31)
RECORD bit.
0 Do not alter the Condition Register.
1 Set Condition Register Field 0.

RX (12:15)
Field used to specify a General Purpose Register in the ranges R0:R7 or R24:R31 to be used as a source or as a destination. R0 is encoded as 0b0000, R1 as 0b0001, etc. R24 is encoded as 0b1000, R25 as 0b1001, etc.

RY (8:11)
Field used to specify a General Purpose Register in the ranges R0:R7 or R24:R31 to be used as a source or as a destination for load/store data. R0 is encoded as 0b0000, R1 as 0b0001, etc. R24 is encoded as 0b1000, R25 as 0b1001, etc.

RZ (8:11)
Field used to specify a General Purpose Register in the ranges R0:R7 or R24:R31 to be used as a source or as a destination for a load/store operation. R0 is encoded as 0b0000, R1 as 0b0001, etc. R24 is encoded as 0b1000, R25 as 0b1001, etc.

SCL (22:23)
Field used to specify a scale amount in Immediate instructions using the SCI8-form. Scaling involves left shifting by 0, 8, 16, or 24 bits.

SD4 (4:7)
Used by 16-bit load and store class instructions. The SD4 field is a 4-bit unsigned immediate value zero-extended to 64 bits, shifted left according to the size of the operation, and then added to the base register to form a 64-bit EA. For byte operations, no shift is performed. For half-word operations, the immediate is shifted left one bit (concatenated with 0b0). For word operations, the immediate is shifted left two bits (concatenated with 0b0).SI (6:10 || 21:31, 11:15 || 21:31)
A 16-bit signed immediate value sign-extended to 64 bits and used as one operand of the instruction.

A 16-bit unsigned immediate value zero-extended to 64 bits or padded with 16 zeros and used as one operand of the instruction. The instruction encoding differs between the I16A and I16L instruction formats as shown in Section 1.4.13 and Section 1.4.14.

UI5 (7:11)
Immediate field used to specify a 5-bit unsigned fixed-point value.

UI7 (5:11)
Immediate field used to specify a 7-bit unsigned fixed-point value.

UI8 (24:31)
Immediate field used to specify an 8-bit unsigned fixed-point value.
For scaled immediate instructions using the \texttt{SCI8}-form, the instruction assembly syntax requires a single immediate value, \texttt{sci8}, that the assembler will synthesize into the appropriate \texttt{F}, \texttt{SCL}, and \texttt{UI8} fields. The \texttt{F}, \texttt{SCL}, and \texttt{UI8} fields must be able to be formed correctly from the given \texttt{sci8} value or the assembler will flag the assembly instruction as an error.
Chapter 2. VLE Storage Addressing

A program references memory using the effective address (EA) computed by the processor when it executes a Storage Access or Branch instruction (or certain other instructions described in Book II and Book III-E), or when it fetches the next sequential instruction.

2.1 Data Storage Addressing Modes

Table 1 lists data storage addressing modes supported by the VLE category.

</tr>
</tbody>
</table>

2.2.1 Misaligned, Mismatched, and Byte Ordering Instruction Storage Exceptions

A Misaligned Instruction Storage Exception occurs when an implementation which supports VLE attempts to execute an instruction that is not 32-bit aligned and the VLE storage attribute is not set for the page that corresponds to the effective address of the instruction. The attempted execution can be the result of a Branch instruction which has bit 62 of the target address set to 1 or the result of an rfi, se_rfi, rfcf, se_rfcf, rfdi, se_rfdi, rfgi, se_rfgi, rfmc, or se_rfmc instruction which has bit 62 set in SRR0, SRR0, CSRRO, CSRRO, DSRR0, DSRR0, GSRRO, GSRRO, MCSRR0, or MCSRRO respectively. If a Misaligned Instruction Storage Exception is detected and no higher priority exception exists, an Instruction Storage Interrupt will occur setting SRR0(GSRR0) to the misaligned address for which execution was attempted.

A Byte Ordering Instruction Storage Exception occurs when an implementation which supports VLE attempts to execute an instruction that has the VLE storage attribute set to 1 and the E (Endian) storage attribute set to 1 for the page that corresponds to the effective address of the instruction. If a Byte Ordering Instruction Storage Exception is detected and no higher priority exception exists, an Instruction Storage Interrupt will occur setting SRR0(GSRR0) to the address for which execution was attempted.

2.2.2 VLE Exception Syndrome Bits

Two bits in the Exception Syndrome Register (ESR) (see Section 7.2.13 of Book III-E) are provided to facilitate VLE exception handling, VLEMI and MIF.

ESR(GESR)_{VLEMI} is set when an exception and subsequent interrupt is caused by the execution or attempted
execution of an instruction that resides in memory with the VLE storage attribute set.

ESR(GESR)_MIF is set when an Instruction Storage Interrupt is caused by a Misaligned Instruction Storage Exception or when an Instruction TLB Error Interrupt was caused by a TLB miss on the second half of a misaligned 32-bit instruction.

ESR(GESR)_BO is set when an Instruction Storage Interrupt is caused by a Mismatched Instruction Storage Exception or a Byte Ordering Instruction Storage Exception.

### Programming Note

When an Instruction TLB Error Interrupt occurs as the result of a Instruction TLB miss on the second half of a 32-bit VLE instruction that is aligned to only 16-bits, SRR0 will point to the first half of the instruction and ESR_MIF will be set to 1. Any other status posted as a result of the TLB miss (such as MAS register updates described in Chapter 6 of Book III-E) will reflect the page corresponding to the second half of the instruction which caused the Instruction TLB miss.
Chapter 3. VLE Compatibility with Books I–III

This chapter addresses the relationship between VLE and Books I–III.

3.1 Overview

Category VLE uses the same semantics as Books I–III. Due to the limited instruction encoding formats, VLE instructions typically support reduced immediate fields and displacements, and not all operations defined by Books I–III are encoded in category VLE. The basic philosophy is to capture all useful operations, with most frequent operations given priority. Immediate fields and displacements are provided to cover the majority of ranges encountered in Embedded control code. Instructions are encoded in either a 16- or 32-bit format, and these may be freely intermixed.

VLE instructions cannot access floating-point registers (FPRs). VLE instructions use GPRs and SPRs with the following limitations:

- VLE instructions using the 16-bit formats are limited to addressing GPR0–GPR7, and GPR24–GPR31 in most instructions. Move instructions are provided to transfer register contents between these registers and GPR8–GPR23.
- VLE compare and bit test instructions using the 16-bit formats implicitly set their results in CR0.

VLE instruction encodings are generally different than instructions defined by Books I–III, except that most instructions falling within primary opcode 31 are encoded identically and have identical semantics unless they affect or access a resource not supported by category VLE.

3.2 VLE Processor and Storage Control Extensions

This section describes additional functionality to support category VLE.

3.2.1 Instruction Extensions

This section describes extensions to support VLE operations. Because instructions may reside on a half-word boundary, bit 62 is not masked by instructions that read an instruction address from a register, such as the LR, CTR, or a save/restore register 0, that holds an instruction address:

The instruction set defined by Books I–III is modified to support halfword instruction addressing, as follows:

- For Return From Interrupt instructions, such as rfi, rfci, rdfi, rfgi, and rfmc, no longer mask bit 62 of the respective save/restore register 0. The destination address is SRR0:62 \(\|\) 0b0, CSRR0:62 \(\|\) 0b0, DSRR0:62 \(\|\) 0b0, GSRR0:62 \(\|\) 0b0, and MCSRR0:62 \(\|\) 0b0, respectively.
- For bclr, bclrl, bcctr, and bcctl no longer mask bit 62 of the LR or CTR. The destination address is LR0:62 \(\|\) 0b0 or CTR0:62 \(\|\) 0b0.

3.2.2 MMU Extensions

VLE operation is indicated by the VLE storage attribute. When the VLE storage attribute for a page is set to 1, instruction fetches from that page are decoded and processed as VLE instructions. See Section 6.8.3 of Book III-E.

When instructions are executing from a page that has the VLE storage attribute set to 1, the processor is said to be in VLE mode.

3.3 VLE Limitations

VLE instruction fetches are valid only when performed in a Big-Endian mode. Attempting to fetch an instruction in a Little-Endian mode from a page with the VLE storage attribute set causes an Instruction Storage Byte-ordering exception.

Support for concurrent modification and execution of VLE instructions is implementation-dependent.
Chapter 4. Branch Operation Instructions

This section defines Branch instructions that can be executed when a processor is in VLE mode and the registers that support them.

4.1 Branch Facility Registers

The registers that support branch operations are:
- Section 4.1.1, “Condition Register (CR)”
- Section 4.1.2, “Link Register (LR)”
- Section 4.1.3, “Count Register (CTR)”

4.1.1 Condition Register (CR)

The Condition Register (CR) is a 32-bit register which reflects the result of certain operations, and provides a mechanism for testing (and branching). The CR is more fully defined in Book I.

Category VLE uses the entire CR, but some comparison operations and all Branch instructions are limited to using CR0–CR3. The full Book I condition register field and logical operations are provided however.

Figure 18. Condition Register

The bits in the Condition Register are grouped into eight 4-bit fields, CR Field 0 (CR0) ... CR Field 7 (CR7), which are set by VLE defined instructions in one of the following ways.
- Specified fields of the condition register can be set by a move to the CR from a GPR (mtcrf, mtocrf).
- A specified CR field can be set by a move to the CR from another CR field (e_mcrf) or from XER32:35 (mcrxr).
- CR field 0 can be set as the implicit result of a fixed-point instruction.
- A specified CR field can be set as the result of a fixed-point compare instruction.
- CR field 0 can be set as the result of a fixed-point bit test instruction.

CR0

Other instructions from implemented categories may also set bits in the CR in the same manner that they would when not in VLE mode.

Instructions are provided to perform logical operations on individual CR bits and to test individual CR bits.

For all fixed-point instructions in which the Rc bit is defined and set, and for e_add2i, e_and2i, and e_and2is, the first three bits of CR field 0 (CR32:34) are set by signed comparison of the result to zero, and the fourth bit of CR field 0 (CR35) is copied from the final state of XERSO. “Result” here refers to the entire 64-bit value placed into the target register in 64-bit mode, and to bits 32:63 of the value placed into the target register in 32-bit mode.

\[
\begin{align*}
\text{if (64-bit mode)} & \quad \text{then } M \leftarrow 0 \\
\text{else } M & \leftarrow 32 \\
\text{if } (\text{target_register})_{M:63} < 0 & \quad \text{then } c \leftarrow 0b100 \\
\text{else if } (\text{target_register})_{M:63} > 0 & \quad \text{then } c \leftarrow 0b010 \\
\text{else} & \quad c \leftarrow 0b001 \\
\text{CR0} & \leftarrow c \parallel XERSO
\end{align*}
\]

If any portion of the result is undefined, the value placed into the first three bits of CR field 0 is undefined.

The bits of CR field 0 are interpreted as shown below.

<table>
<thead>
<tr>
<th>CR Bit</th>

</tr>
</tbody>
</table>

4.1.1.1 Condition Register Setting for Compare Instructions

For compare instructions, a CR field specified by the BF operand for the e_cmph, e_cmphl, e_cmpi, and e_cmpli instructions, or CR0 for the se_cmpl, e_cmph16i, e_cmphl16i, e_cmpl16i, se_cmph, se_cmphl, se_cmpl, and se_cmpli instructions, is set to reflect the result of the comparison. The CR field bits are interpreted as shown below. A complete description of how the bits are set is...
given in the instruction descriptions and Section 5.6, "Fixed-Point Compare and Bit Test Instructions".

Condition register bits settings for compare instructions are interpreted as follows. (Note: e_cmpl, and e_cmpli instructions have a BF32 field instead of BF field; for these instructions, BF32 should be substituted for BF in the list below.)

**CR Bit Description**

4×BF + 32

*Less Than* (LT)
- For signed fixed-point compare, (RA) or (RX) < sc18, SI, (RB), or (RY).
- For unsigned fixed-point compare, (RA) or (RX) <u sc18, UI, UI5, (RB), or (RY).

4×BF + 33

*Greater Than* (GT)
- For signed fixed-point compare, (RA) or (RX) > sc18, SI, (RB), or (RY).
- For unsigned fixed-point compare, (RA) or (RX) >u sc18, UI, UI5, (RB), or (RY).

4×BF + 34

*Equal* (EQ)
- For fixed-point compare, (RA) or (RX) = sc18, UI, UI5, SI, (RB), or (RY).

4×BF + 35

*Summary Overflow* (SO)
- For fixed-point compare, this is a copy of the contents of XERSO at the completion of the instruction.

**4.1.1.2 Condition Register Setting for the Bit Test Instruction**

The Bit Test Immediate instruction, se_btsti, also sets CR field 0. See the instruction description and also Section 5.6, "Fixed-Point Compare and Bit Test Instructions".

**4.1.2 Link Register (LR)**

VLE instructions use the Link Register (LR) as defined in Book I, although category VLE defines a subset of all variants of Book I conditional branches involving the LR.

**4.1.3 Count Register (CTR)**

VLE instructions use the Count Register (CTR) as defined in Book I, although category VLE defines a subset of the variants of Book I conditional branches involving the CTR.
4.2 Branch Instructions

The sequence of instruction execution can be changed by the branch instructions. Because VLE instructions must be aligned on half-word boundaries, the low-order bit of the generated branch target address is forced to 0 by the processor in performing the branch.

The branch instructions compute the EA of the target in one of the following ways, as described in Section 2.2, "Instruction Storage Addressing Modes".

1. Adding a displacement to the address of the branch instruction.
2. Using the address contained in the LR (Branch to Link Register [and Link]).
3. Using the address contained in the CTR (Branch to Count Register [and Link]).

Branching can be conditional or unconditional, and the return address can optionally be provided. If the return address is to be provided (LK = 1), the EA of the instruction following the branch instruction is placed into the LR after the branch target address has been computed; this is done regardless of whether the branch is taken.

In branch conditional instructions, the BI32 or BI16 instruction field specifies the CR bit to be tested. For 32-bit instructions using BI32, CR32:47 (corresponding to bits in CR0:CR3) may be specified. For 16-bit instructions using BI16, only CR32:35 (bits within CR0) may be specified.

In branch conditional instructions, the BO32 or BO16 field specifies the conditions under which the branch is taken and how the branch is affected by or affects the CR and CTR. Note that VLE instructions also have different encodings for the BO32 and BO16 fields than in Book I's BO field.

If the BO32 field specifies that the CTR is to be decremented, in 64-bit mode CTR0:63 are decremented, and in 32-bit mode CTR32:63 are decremented. If BO16 or BO32 specifies a condition that must be TRUE or FALSE, that condition is obtained from the contents of CRBI32+32 or CRBI16+32. (Note that CR bits are numbered 32:63. BI32 or BI16 refers to the condition register bit field in the branch instruction encoding. For example, specifying BI32 = 2 refers to CR34.)

Encodings for the BO32 field for VLE are shown in Figure 19.

<table>
<thead>
<tr>

cond_ok $\leftarrow (\text{CRBI16+32} = \text{BO16})$

if cond_ok then

NIA $\leftarrow_{\text{iens}} \text{CIA + EXTS (BD8 || 0b0)}$

else

NIA $\leftarrow_{\text{iens}} \text{CIA + 2}$

The BI16 field specifies the Condition Register bit to be tested. The BO16 field is used to resolve the branch as described in Figure 20. **target_addr** specifies the branch target address.

The branch target address is the sum of BD8 || 0b0 sign-extended and the address of this instruction, with the high-order 32 bits of the branch target address set to 0 in 32-bit mode.

**Special Registers Altered:**

None
Branch to Count Register [and Link] C-form

se_bctr (LK=0)
se_bctrl (LK=1)

NIA ← lea CTR0:62 || 0b0
if LK then LR ← lea CIA + 2

The branch target address is CTR0:62 || 0b0 with the high-order 32 bits of the branch target address set to 0 in 32-bit mode.

If LK=1 then the effective address of the instruction following the Branch instruction is placed into the Link Register.

Special Registers Altered:
LR (if LK=1)

Branch to Link Register [and Link] C-form

se_blr (LK=0)
se_brlr (LK=1)

NIA ← lea LR0:62 || 0b0
if LK then LR ← lea CIA + 2

The branch target address is LR0:62 || 0b0 with the high-order 32 bits of the branch target address set to 0 in 32-bit mode.

If LK=1 then the effective address of the instruction following the Branch instruction is placed into the Link Register.

Special Registers Altered:
LR (if LK=1)
4.3 System Linkage Instructions

The System Linkage instructions enable the program to call upon the system to perform a service and provide a means by which the system can return from performing a service or from processing an interrupt. System Linkage instructions defined by the VLE category are identical in semantics to System Linkage instructions defined in Book I and Book III-E with the exception of the LEV field, but are encoded differently.

**se_sc** provides the same functionality as the Book I (and Book III-E) instruction *sc* without the LEV field. **se_rfi, se_rfci, se_rfdi,** and **se_rfmci** provide the same functionality as the Book III-E instructions *rfi, rfci, rfdi,* and *rfmci* respectively.

---

**System Call**  
**C-form,ESC-form**

<table>
<thead>
<tr>

<th>02 15</th>
</tr>
</thead>
<tbody>
<tr>
<td>ELEV [Category:Embedded.Hypervisor]</td>
<td></td>
</tr>
</tbody>
</table>

**e_sc**  

- ELEV 36

- if ELEV = 1 then
  - MSR = ELEV

  //
  31 6 11 16 21 31

- If MSRGS = 0 or if ELEV = 1, the effective address of the instruction following the System Call instruction is placed into SRR0 and the contents of the MSR are copied into SRR1. Otherwise, the effective address of the instruction following the System Call instruction is placed into GSRR0 and the contents of the MSR are copied into GSRR1. ELEV values greater than 1 are reserved. Bits 0:3 of the ELEV field (instruction bits 16:19) are treated as a reserved field.

- If ELEV=0, a System Call interrupt is generated. If ELEV=1, an Embedded Hypervisor System Call interrupt is generated. The interrupt causes the MSR to be set as described in Section 7.6.10 and Section 7.6.30 of Book III-E.

- If MSRGS = 0 or *se_sc* is executed, and the processor is in guest state, instruction execution resumes at the address given by one of the following.
  - GIVPR0:47 || GIVOR8:59||0b0000 if IVORS [Category:Embedded.Phased-Out] are supported.
  - GIVPR0:51||0x120 if Interrupt Fixed Offsets [Category:Embedded.Phased-In] are supported.

- If MSRGS = 0 or *se_sc* is executed, and the processor is in hypervisor state, instruction execution resumes at the address given by one of the following.
  - IVPR0:47 || IVOR8:59||0b0000 if IVORS [Category:Embedded.Phased-Out] are supported.
  - IVPR0:51||0x120 if Interrupt Fixed Offsets [Category:Embedded.Phased-In] are supported.

- If ELEV=1, the interrupt causes instruction execution to resume at the address given by one of the following.
  - GIVPR0:47 || GIVOR8:59||0b0000 if IVORS [Category:Embedded.Phased-Out] are supported.
  - GIVPR0:51||0x300 if Interrupt Fixed Offsets [Category:Embedded.Phased-In] are supported.

This instruction is context synchronizing.

**Special Registers Altered:**  
SRR0 GSRR0 SRR1 GSRR1 MSR

---

**Programming Note**

*e_sc* serves as both a basic and an extended mnemonic. The Assembler will recognize an *e_sc* mnemonic with one operand as the basic form, and an *e_sc* mnemonic with no operand as the extended form. In the extended form, the ELEV operand is omitted and assumed to be 0.
**Illegal**

\[se\text{\_illega}l\]

\[\begin{array}{c}

**Return From Machine Check Interrupt**

**C-form**

\[se\text{\_rfmci}\]

\[\begin{array}{c}
<table>
<thead>
<tr>
<th>\text{Code}</th>
<th>\text{Size}</th>
</tr>
</thead>
<tbody>
<tr>
<td>11</td>
<td>15</td>
</tr>
</tbody>
</table>
\end{array}\]

The \textit{se\_rfmci} instruction is used to return from a machine check class interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously.

The contents of MCSRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address MCSRR0\_0:62||0b0. If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the values placed into the save/restore registers by the interrupt processing mechanism (see Chapter 7 of Book III-E) is the address and MSR value of the instruction that would have been executed next had the interrupt not occurred (that is, the address in MCSRR0 at the time of the execution of the \textit{se\_rfmci}).

This instruction is privileged and context synchronizing.

**Special Registers Altered:**
- MSR
## Return From Critical Interrupt C-form

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Description</th>
</tr>

<td>The <code>se_rfi</code> instruction is used to return from a non-critical class interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously. The contents of SRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched under control of the new MSR value from the address SRR0_0.62</td>
</tr>
</tbody>
</table>
The `se_rfdi` instruction is used to return from a debug class interrupt, or as a means of establishing a new context and synchronizing on that new context simultaneously.

The contents of DSRR1 are placed into the MSR. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address DSRR0:62||0b0. If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into the save/restore registers by the interrupt processing mechanism (see Chapter 7 of Book III-E) is the address of the instruction that would have been executed next had the interrupt not occurred (that is, the address in DSRR0 at the time of the execution of `se_rfdi`).

This instruction is privileged and context synchronizing.

Special Registers Altered:
MSR

Corequisite Categories:
Embedded. Enhanced Debug

---

The `se_rfgi` instruction is used to return from a guest state base class interrupt, or as a means of simultaneously establishing a new context and synchronizing on that new context.

The contents of Guest Save/Restore Register 1 are placed into the MSR. If the `se_rfgi` is executed in the guest supervisor state (MSR GS PR = 0b10), the bits MSR GS WE are not modified and the bits MSR UCLE DE PMM are modified only if the associated bits in the Machine State Register Protect (MSRP) Register are set to 0. If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address GSRR0:62||0b0. If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into the associated save/restore register 0 by the interrupt processing mechanism is the address of the instruction that would have been executed next had the interrupt not occurred (i.e. the address in GSRR0 at the time of the execution of `se_rfgi`).

This instruction is privileged and context synchronizing.

Special Registers Altered:

4.4 Condition Register Instructions

Condition Register instructions are provided to transfer values to and from various portions of the CR. Category VLE does not introduce any additional functionality beyond that defined in Book I for CR operations, but does remap the CR-logical and mcrf instruction functionality into primary opcode 31. These instructions operate identically to the Book I instructions, but are encoded differently.

### Condition Register AND XL-form

**e_crand**  
BT, BA, BB

<table>
<thead>
<tr>
<th>31</th>
<th>BT</th>
<th>BA</th>
<th>BB</th>
<th>257</th>
</tr>
</thead>
</table>

\[ \text{CR}_{\text{BT+32}} \leftarrow \text{CR}_{\text{BA+32}} \& \text{CR}_{\text{BB+32}} \]

The bit in the Condition Register specified by BA+32 is ANDed with the bit in the Condition Register specified by BB+32, and the result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**

\[ \text{CR}_{\text{BT+32}} \]

### Condition Register AND with Complement XL-form

**e_crandc**  
BT, BA, BB

<table>
<thead>
<tr>
<th>31</th>
<th>BT</th>
<th>BA</th>
<th>BB</th>
<th>129</th>
</tr>
</thead>
</table>

\[ \text{CR}_{\text{BT+32}} \leftarrow \text{CR}_{\text{BA+32}} \& \neg \text{CR}_{\text{BB+32}} \]

The bit in the Condition Register specified by BA+32 is ANDed with the one's complement of the bit in the Condition Register specified by BB+32, and the result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**

\[ \text{CR}_{\text{BT+32}} \]

### Condition Register Equivalent XL-form

**e_creqv**  
BT, BA, BB

<table>
<thead>
<tr>
<th>31</th>
<th>BT</th>
<th>BA</th>
<th>BB</th>
<th>289</th>
</tr>
</thead>
</table>

\[ \text{CR}_{\text{BT+32}} \leftarrow \text{CR}_{\text{BA+32}} \equiv \text{CR}_{\text{BB+32}} \]

The bit in the Condition Register specified by BA+32 is XORed with the bit in the Condition Register specified by BB+32, and the complemented result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**

\[ \text{CR}_{\text{BT+32}} \]

### Condition Register NAND XL-form

**e_crnand**  
BT, BA, BB

<table>
<thead>
<tr>
<th>31</th>
<th>BT</th>
<th>BA</th>
<th>BB</th>
<th>225</th>
</tr>
</thead>
</table>

\[ \text{CR}_{\text{BT+32}} \leftarrow \neg (\text{CR}_{\text{BA+32}} \& \text{CR}_{\text{BB+32}}) \]

The bit in the Condition Register specified by BA+32 is ANDed with the bit in the Condition Register specified by BB+32, and the complemented result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**

\[ \text{CR}_{\text{BT+32}} \]
**Condition Register NOR**  
**XL-form**

\[
e_{\text{cnor}} \quad \text{BT,BA,BB}
\]

\[
\begin{array}{cccccc}
31 & BT & BA & BB & 33 \\
\end{array}
\]

\[
\text{CR}_{BT+32} \leftarrow \neg (\text{CR}_{BA+32} \mid \text{CR}_{BB+32})
\]

The bit in the Condition Register specified by BA+32 is ORed with the bit in the Condition Register specified by BB+32, and the complemented result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**  
\[\text{CR}_{BT+32}\]

**Condition Register OR with Complement**  
**XL-form**

\[
e_{\text{corc}} \quad \text{BT,BA,BB}
\]

\[
\begin{array}{cccccc}
31 & BT & BA & BB & 417 \\
\end{array}
\]

\[
\text{CR}_{BT+32} \leftarrow \text{CR}_{BA+32} \mid \neg \text{CR}_{BB+32}
\]

The bit in the Condition Register specified by BA+32 is ORed with the complement of the bit in the Condition Register specified by BB+32, and the result is placed into the bit in the Condition Register specified by BT+32.

**Special Registers Altered:**  
\[\text{CR}_{BT+32}\]

**Move CR Field**  
**XL-form**

\[
e_{\text{mcr}} \quad \text{BF,BFA}
\]

\[
\begin{array}{cccccc}
31 & BF & /// & BFA & /// & 16 \\

\]

\[
\text{CR}_{4x\text{BF}+32;4x\text{BF}+35} \leftarrow \text{CR}_{4x\text{BFA}+32;4x\text{BFA}+35}
\]

The contents of Condition Register field BFA are copied to Condition Register field BF.

**Special Registers Altered:**  
\[\text{CR field BF}\]
Chapter 5. Fixed-Point Instructions

This section lists the fixed-point instructions supported by category VLE.

5.1 Fixed-Point Load Instructions

The fixed-point Load instructions compute the effective address (EA) of the memory to be accessed as described in Section 2.1, “Data Storage Addressing Modes”.

The byte, halfword, word, or doubleword in storage addressed by EA is loaded into RT or RZ.

Category VLE supports both Big- and Little-Endian byte ordering for data accesses.

Some fixed-point load instructions have an update form in which RA is updated with the EA. For these forms, if RA≠0 and RA≠RT, the EA is placed into RA and the memory element (byte, halfword, word, or doubleword) addressed by EA is loaded into RT. If RA=0 or RA =RT, the instruction form is invalid. This is the same behavior as specified for load with update instructions in Book I.

The fixed-point Load instructions from Book I, lbzx, lhzx, lhzx, lhax, lhau, lwzx, and lwzux are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I. See Section 3.3.2 of Book I for the instruction definitions.

The fixed-point Load instructions from Book I, lwax, lwaux, ldx, and ldux are available while executing in VLE mode on 64-bit implementations. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I. See Section 3.3.2 of Book I for the instruction definitions.
### Load Byte and Zero D-form

- **Syntax:**
  
  ```
  e_lbz     RT,D(RA)
  ```

- **Operands:**
  
  - `RT`: Destination register
  - `D`: Immediate data
  - `RA`: Source register

- **Instructions:**
  
  ```
  12  RT  RA  D  31
  ```

- **Operation:**
  
  - If RA = 0 then b ← 0
  - Else b ← {RA}
  - EA ← b + EXTS(D)
  - RT ← 00 || MEM(EA, 1)

- **Effect:**
  
  Let the effective address (EA) be the sum (RA0) + D. The byte in storage addressed by EA is loaded into RT56:63. RT0:55 are set to 0.

- **Special Registers Altered:**
  
  None

### Load Halfword Algebraic D-form

- **Syntax:**
  
  ```
  e_lha     RT,D(RA)
  ```

- **Operands:**
  
  - `RT`: Destination register
  - `D`: Immediate data
  - `RA`: Source register

- **Instructions:**
  
  ```
  06  RT  RA  0  D8  31
  ```

- **Operation:**
  
  ```
  EA ← (RA) + EXTS(D8)
  RT ← 00 || MEM(EA, 1)
  RA ← EA
  ```

- **Effect:**
  
  Let the effective address (EA) be the sum (RA) + D8. The byte in storage addressed by EA is loaded into RT56:63. RT0:55 are set to 0.
  
  EA is placed into register RA.

- **Special Registers Altered:**
  
  None

### Load Byte and Zero Short Form SD4-form

- **Syntax:**
  
  ```
  se_lbz    RZ,SD4(RX)
  ```

- **Operands:**
  
  - `RZ`: Destination register
  - `SD4`: Immediate data
  - `RX`: Source register

- **Instructions:**
  
  ```
  08  SD4  RZ  RX  15
  ```

- **Operation:**
  
  ```
  EA ← (RX) + 00 || SD4
  RZ ← 00 || MEM(EA, 1)
  ```

- **Effect:**
  
  Let the effective address (EA) be the sum RX + SD4. The byte in storage addressed by EA is loaded into RT56:63. RT0:55 are set to 0.

- **Special Registers Altered:**
  
  None

### Load Halfword Algebraic Short Form SD4-form

- **Syntax:**
  
  ```
  se_lhz    RZ,SD4(RX)
  ```

- **Operands:**
  
  - `RZ`: Destination register
  - `SD4`: Immediate data
  - `RX`: Source register

- **Instructions:**
  
  ```
  10  SD4  RZ  RX  15
  ```

- **Operation:**
  
  ```
  EA ← (RX) + 00 || SD4
  RZ ← 00 || MEM(EA, 1)
  ```

- **Effect:**
  
  Let the effective address (EA) be the sum RX + (SD4 || 0). The halfword in storage addressed by EA is loaded into RZ48:63. RZ0:47 are set to 0.

- **Special Registers Altered:**
  
  None

**Power ISA™ - Book VLE**

**1286**
Load Halfword Algebraic with Update

\[ e_{lhau} \quad RT,D8(RA) \]

\[ \begin{array}{cccccc}
0 & 6 & RT & RA & 0 & 3 & D8 \\
\end{array} \]

\[ \begin{align*}
EA & \leftarrow (RA) + \text{EXTS}(D8) \\
RT & \leftarrow \text{EXTS} (\text{MEM}(EA, 2)) \\
RA & \leftarrow EA
\end{align*} \]

Let the effective address (EA) be the sum (RA) + D8. The halfword in storage addressed by EA is loaded into RT_{48:63}. RT_{0:47} are filled with a copy of bit 0 of the loaded halfword.

EA is placed into RA.

If RA = 0 or RA = RT, the instruction form is invalid.

Special Registers Altered:
None

Load Halfword and Zero with Update

\[ e_{lhzu} \quad RT,D8(RA) \]

\[ \begin{array}{cccccc}
0 & 6 & RT & RA & 0 & 1 & D8 \\
\end{array} \]

\[ \begin{align*}
EA & \leftarrow (RA) + \text{EXTS}(D8) \\
RT & \leftarrow 00 \| \text{MEM}(EA, 2) \\
RA & \leftarrow EA
\end{align*} \]

Let the effective address (EA) be the sum (RA) + D8. The halfword in storage addressed by EA is loaded into RT_{48:63}. RT_{0:47} are set to 0.

EA is placed into register RA.

If RA = 0 or RA = RT, the instruction form is invalid.

Special Registers Altered:
None

Load Word and Zero

\[ e_{lwz} \quad RT,D(RA) \]

\[ \begin{array}{cccc}
20 & RT & RA \\
\end{array} \]

if RA = 0 then \[ b \leftarrow 0 \]
else \[ b \leftarrow (RA) \]

\[ EA \leftarrow b + \text{EXTS}(D) \\
RT \leftarrow 00 \| \text{MEM}(EA, 4) \]

Let the effective address (EA) be the sum (RA|0) + D. The word in storage addressed by EA is loaded into RT_{32:63}. RT_{0:31} are set to 0.

Special Registers Altered:
None

Load Word and Zero Short Form

\[ se_{lwz} \quad RZ,SD4(RX) \]

\[ \begin{array}{cccc}
12 & SD4 & RZ & RX \\
\end{array} \]

\[ \begin{align*}
EA & \leftarrow (RX) + (SD4 \| 00) \\
RZ & \leftarrow 00 \| \text{MEM}(EA, 2)
\end{align*} \]

Let the effective address (EA) be the sum (RX) + (SD4 \| 00). The word in storage addressed by EA is loaded into RZ_{32:63}. RZ_{0:31} are set to 0.

Special Registers Altered:
None
Load Word and Zero with Update D8-form

e_lwzu      RT,D8(RA)

Let the effective address (EA) be the sum (RA) + D8. The word in storage addressed by EA is loaded into RT32:63. RT0:31 are set to 0.

EA is placed into register RA.

If RA=0 or RA=RT, the instruction form is invalid.

Special Registers Altered:
None
5.2 Fixed-Point Store Instructions

The fixed-point Store instructions compute the EA of the memory to be accessed as described in Section 2.1, “Data Storage Addressing Modes”.

The contents of register RS or RZ are stored into the byte, halfword, word, or doubleword in storage addressed by EA.

Category VLE supports both Big- and Little-Endian byte ordering for data accesses.

Some fixed-point store instructions have an update form, in which register RA is updated with the effective address. For these forms, the following rules (from Book I) apply.

- If RA≠0, the effective address is placed into register RA.
- If RS=RA, the contents of register RS are copied to the target memory element and then EA is placed into register RA (RS).

The fixed-point Store instructions from Book I, stbx, stbux, sthx, sthux, stwx, and stwux are available while executing in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Section 3.3.3 of Book I for the instruction definitions.

The fixed-point Store instructions from Book I, stdx and stdux are available while executing in VLE mode on 64-bit implementations. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I; see Section 3.3.3 of Book I for the instruction definitions.

### Store Byte

<tr>
<th>D-form</th>
</tr>
</thead>
<tbody>
<tr>
<td>e_stb</td>
</tr>
</tbody>
</table>

if RA = 0 then b ← 0
else b ← (RA)
EA ← b + EXTS(D)
MEM(EA, 1) ← (RS)_{56:63}

Let the effective address (EA) be the sum (RAi0)+ D. (RS)_{56:63} are stored in the byte in storage addressed by EA.

**Special Registers Altered:**

None

### Store Byte Short Form

<table>
<thead>
<tr>
<th>D4-form</th>
</tr>
</thead>
<tbody>
<tr>
<td>se_stb</td>
</tr>
</tbody>
</table>

EA ← (RX) + EXTS(SD4)
MEM(EA, 1) ← (RZ)_{56:63}

Let the effective address (EA) be the sum (RX) + SD4. (RZ)_{56:63} are stored in the byte in storage addressed by EA.

**Special Registers Altered:**

None
Store Byte with Update\hspace{1cm}D8-form

\textbf{e\textunderscore stbu } RS,D8(RA)

\begin{tabular}{cccccc}
   & 06 & RS & RA & 04 & D8 \\
\hline
\end{tabular}

EA & \leftarrow (RX) + (^{23}_{0} \| \text{SD4} \| 0) \\
\text{MEM}(EA, 2) & \leftarrow (RZ)_{48:63}
\end{align*}

Let the effective address (EA) be the sum (RX) + (SD4 \| 0). (RZ)_{48:63} are stored in the halfword in storage addressed by EA.

Special Registers Altered:
None

Store Halfword with Update\hspace{1cm}D8-form

\textbf{e\textunderscore sthu } RS,D8(RA)

\begin{tabular}{cccccc}
   & 06 & RS & RA & 05 & D8 \\
\hline
\end{tabular}

\begin{align*}
EA & \leftarrow (RA) + \text{EXTS}(D8) \\
\text{MEM}(EA, 2) & \leftarrow (RS)_{48:63} \\
RA & \leftarrow EA
\end{align*}

Let the effective address (EA) be the sum (RA) + D8. (RS)_{48:63} are stored in the halfword in storage addressed by EA.

EA is placed into register RA.

If RA=0, the instruction form is invalid.

Special Registers Altered:
None
### Store Word

**D-form**

<table>
<thead>
<tr>
<th></th>
<th>21</th>
<th>RS</th>
<th>RA</th>
<th>16</th>
<th>D</th>
</tr>
</thead>
</table>

- **e_stw** RS,D(RA)

  if RA = 0 then b ← 0
  else b ← (RA)
  EA ← b + EXTS(D)
  MEM(EA, 4) ← (RS)_{32:63}

Let the effective address (EA) be the sum (RA)₀ + D. (RS)_{32:63} are stored in the word in storage addressed by EA.

**Special Registers Altered:**

None

### Store Word Short Form

**SD4-form**

<table>
<thead>
<tr>
<th>13</th>
<th>SD4</th>
<th>RZ</th>
<th>RX</th>
</tr>
</thead>
</table>

- **se_stw** RZ,SD4(RX)

  EA ← (RX) + (580 | SD4 | 20)
  MEM(EA, 4) ← (RZ)_{32:63}

Let the effective address (EA) be the sum (RX)₀ + (SD4 | 00). (RZ)_{32:63} are stored in the word in storage addressed by EA.

**Special Registers Altered:**

None

### Store Word with Update

**D8-form**

<table>
<thead>
<tr>
<th>06</th>
<th>06</th>
<th>D8</th>
</tr>
</thead>
</table>

- **e_stwu** RS,D8(RA)

  EA ← (RA) + EXTS(D8)
  MEM(EA, 4) ← (RS)_{32:63}
  RA ← EA

Let the effective address (EA) be the sum (RA)₀ + D8. (RS)_{32:63} are stored in the word in storage addressed by EA.

EA is placed into register RA.

If RA=0, the instruction form is invalid.

**Special Registers Altered:**

None
5.3 Fixed-Point Load and Store with Byte Reversal Instructions

The fixed-point Load with Byte Reversal and Store with Byte Reversal instructions from Book I, \texttt{lhbrx}, \texttt{lwbrx}, \texttt{sthbrx}, and \texttt{stwbrx} are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I. See Section 3.3.5 of Book I for the instruction definitions.

5.4 Fixed-Point Load and Store Multiple Instructions

The Load/Store Multiple instructions have preferred forms; see Section 1.8.1 of Book I. In the preferred forms storage alignment satisfies the following rule.

- The combination of the EA and RT (RS) is such that the low-order byte of GPR 31 is loaded (stored) from (into) the last byte of an aligned quadword in storage.

\begin{tabular}{|c|c|c|c|c|c|}
\hline
\textbf{Load Multiple Word} & \textbf{D8-form} & \textbf{Store Multiple Word} & \textbf{D8-form} \\
\hline
\texttt{e_lmw} & \texttt{RT,D8(RA)} & \texttt{e_stmw} & \texttt{RS,D8(RA)} \\
\hline
0  & 6 & RT & 11 & RA & 16 & 08 & 24 & D8 \\
0  & 6 & RS & 11 & RA & 16 & 09 & 24 & D8 \\
\hline
\end{tabular}

\[
\begin{align*}
\text{if } RA = 0 & \text{ then } b \leftarrow 0 \\
\text{else} & \quad b \leftarrow \text{(RA)} \\
\text{EA} & \leftarrow b + \text{EXTS(D8)} \\
r & \leftarrow RT \\
\text{do while } r \leq 31 \\
& \quad \text{GPR}(r) \leftarrow \ll_{16} \| \text{MEM}(EA, 4) \\
r & \leftarrow r + 1 \\
\text{EA} & \leftarrow \text{EA} + 4 \\
\end{align*}
\]

Let \( n = (32 - RT) \). Let the effective address (EA) be the sum (RA(0) + D8).

\( n \) consecutive words starting at EA are loaded into the low-order 32 bits of GPRs RT through 31. The high-order 32 bits of these GPRs are set to zero.

If RA is in the range of registers to be loaded, including the case in which RA = 0, the instruction form is invalid.

\textbf{Special Registers Altered:}

None
5.5 Fixed-Point Arithmetic Instructions

The fixed-point Arithmetic instructions use the contents of the GPRs as source operands, and place results into GPRs, into status bits in the XER and into CR0.

The fixed-point Arithmetic instructions treat source operands as signed integers unless the instruction is explicitly identified as performing an unsigned operation.

The e_add2i instruction and other Arithmetic instructions with Rc=1 set the first three bits of CR0 to characterize the result placed into the target register. In 64-bit mode, these bits are set by signed comparison of the result to 0. In 32-bit mode, these bits are set by signed comparison of the low-order 32 bits of the result to zero.

e_addi[,] and e_subfi[,] always set CA to reflect the carry out of bit 0 in 64-bit mode and out of bit 32 in 32-bit mode.

The fixed-point Arithmetic instructions from Book I, add[,], addo[,], addci[,], addco[,], addi[,], addo[,], addmi[,], addmei[,], addmeo[,], addzei[,], addzeo[,], divw[,], divwo[,], divwu[,], mulhw[,], mulhwu[,], mulw[,], mulwo[,], neg[,], nego[,], subf[,], subfo[,], subfe[,], subfco[,], subfze[,], subfzeo[,], subfc[,], and subfco[,] are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I; see Section 3.3.9 of Book I for the instruction definitions.

The fixed-point Arithmetic instructions from Book I, mulld[,], mulldo[,], mulhld[,], mulhdu[,], muld[,], muldou[,], divd[,], divdu[,], and divdou[,] are available while executing in VLE mode on 64-bit implementations. The mnemonics, decoding, and semantics for those instructions are identical to these in Book I; see Section 3.3.9 of Book I for the instruction definitions.
Add Short Form

\textbf{RR-form}

\begin{itemize}
  \item se\_add RX,RY
  \begin{tabular}{cccc}
    01 & 0 & RX & RY
  \end{tabular}
  \end{itemize}

The sum (RX + RY) is placed into register RX.

Special Registers Altered:

\begin{itemize}
  \item None
\end{itemize}

Add Immediate

\textbf{D-form}

\begin{itemize}
  \item e\_add16i RT,RA,SI
  \begin{tabular}{cccc}
    07 & RT & RA & SI
  \end{tabular}

Rc & OIM5 & RX \\
\end{array}
\]

oimm \leftarrow \frac{59}{} \ || \ OIM5 + 1

RX \leftarrow (RX) + \neg(oimm) + 1

The sum (RA) + \neg(oimm) + 1 is placed into register RX.

The value of oimm must be in the range 1 to 32.

Special Registers Altered:
- CR0 (if Rc=1)
Multiply Low Scaled Immediate SCI8-form

e_mulli RT,RA,sci8

```
  06  RT  RA  20  F  SCL  UI8
```

```
scli8 ← 56-SCL×F || UI8 || SCL×8
prod[0:127] ← (RA) × sci8
RT ← prod[64:127]
```

The 64-bit first operand is (RA). The 64-bit second operand is the sci8 operand. The low-order 64-bits of the 128-bit product of the operands are placed into register RT.

Both operands and the product are interpreted as signed integers.

**Special Registers Altered:**

None

Multiply (2 operand) Low Immediate I16A-form

e_mulli2i RA,si

```
  28  si  RA  20  si
```

```
prod[0:127] ← (RA) × EXTS(si)
RA ← prod[64:127]
```

The 64-bit first operand is (RA). The 64-bit second operand is the sign-extended value of the si operand. The low-order 64-bits of the 128-bit product of the operands are placed into register RA.

Both operands and the product are interpreted as signed integers.

**Special Registers Altered:**

None

Multiply Low Word Short Form RR-form

se_mullw RX,RY

```
  01  RX  RY
```

```
RX ← (RX)32:63 × (RY)32:63
```

The 32-bit operands are the low-order 32-bits of RX and of RY. The 64-bit product of the operands is placed into register RX.

Both operands and the product are interpreted as signed integers.

**Special Registers Altered:**

None

Negate Short Form R-form

se_neg RX

```
  03  RX
```

```
RX ← ¬(RX) + 1
```

The sum ¬(RX) + 1 is placed into register RX.

If the processor is in 64-bit mode and register RX contains the most negative 64-bit number (0x8000_0000_0000_0000), the result is the most negative 64-bit number. Similarly, if the processor is in 32-bit mode and register RX contains the most negative 32-bit number (0x8000_0000), the result is the most negative 32-bit number.

**Special Registers Altered:**

None
5.6 Fixed-Point Compare and Bit Test Instructions

The fixed-point Compare instructions compare the contents of register RA or register RX with one of the following:

- The value of the scaled immediate field $sci_8$ formed from the F, UI8, and SCL fields as:
  
  $sci_8 = 56 \times SCL \times F \ || \ UI8 \ || SCL \times F$

- The zero-extended value of the UI field
- The zero-extended value of the UI5 field
- The sign-extended value of the SI field
- The contents of register RB or register RY.

The following comparisons are signed: $e_{cmph}$, $e_{cmp}$, $e_{cmp16i}$, $e_{cmph16i}$, $se_{cmp}$, $se_{cmph}$, and $se_{cmp16}$.

The following comparisons are unsigned: $e_{cmpl}$, $e_{cmpli}$, $e_{cmpl16i}$, $e_{cmpl16i}$, $se_{cmpl}$, $se_{cmpli}$, and $se_{cmpl16}$.

The fixed-point Bit Test instruction tests the bit specified by the UI5 instruction field and sets the CR0 field as follows.

<table>
<thead>
<tr>
<th>Bit Name Description</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0 LT</td>
<td>Always set to 0</td>
</tr>
<tr>
<td>1 GT</td>
<td>RX_{ui5} = 1</td>
</tr>
<tr>
<td>2 EQ</td>
<td>RX_{ui5} = 0</td>
</tr>
<tr>
<td>3 SO</td>
<td>Summary overflow from the XER</td>
</tr>
</tbody>
</table>

The fixed-point Compare instructions from Book I, $cmp$ and $cmpl$ are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I; see Section 3.3.10 of Book I for the instruction definitions.

### Bit Test Immediate

**IM5-form**

<table>
<thead>
<tr>
<th>se_BTSTI</th>
<th>RX,UI5</th>
</tr>
</thead>
<tbody>
<tr>
<td>25</td>
<td>1</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>UI5</th>
<th>RX</th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td>0</td>
</tr>
</tbody>
</table>

- $a \leftarrow UI5$
- $b \leftarrow a^{31:0} || 0^{31:0}$
- $c \leftarrow (RX) \ & \ b$
- if $c = 0$ then $d \leftarrow 0b001$ else $d \leftarrow 0b101$
- $CR0 \leftarrow d \ || XER_{SO}$

Bit UI5+32 of register RX is tested for equality to '0' and the result is recorded in CR0. EQ is set if the tested bit is 0, LT is cleared, and GT is set to the inverse value of EQ.

**Special Registers Altered:**

- CR0

### Compare Immediate Word

**I16A-form**

<table>
<thead>
<tr>
<th>e_cmp16i</th>
<th>RA,si</th>
</tr>
</thead>
<tbody>
<tr>

**Chapter 5. Fixed-Point Instructions**

### 5.7 Fixed-Point Trap Instructions

The fixed-point Trap instruction from Book I, `tw` is available while executing in VLE mode. The mnemonics, decoding, and semantics for this instruction is identical to that in Book I; see Section 3.3.11 of Book I for the instruction definition.

The fixed-point Trap instruction from Book I, `td` is available while executing in VLE mode on 64-bit implementations. The mnemonic, decoding, and semantics for the `td` instruction are identical to those in Book I; see Section 3.3.11 of Book I for the instruction definitions.

### 5.8 Fixed-Point Select Instruction

The fixed-point Select instruction provides a means to select one of two registers and place the result in a destination register under the control of a predicate value supplied by a CR bit.

The fixed-point Select instruction from Book I, `isel` is available while executing in VLE mode. The mnemonics, decoding, and semantics for this instruction is identical to that in Book I; see Section of Book I for the instruction definition.

---

**Compare Halfword Logical Immediate**

**I16A-form**

```
e_cmphl16i RA, ui
```

<table>
<thead>

- if \( a >_u b \) then \( c \leftarrow 0b010 \)
- if \( a = b \) then \( c \leftarrow 0b001 \)
- \( CR0 \leftarrow c \parallel XER_{60} \)

The low-order 16 bits of register RA are compared with the `ui` field, treating operands as signed integers. The result of the comparison is placed into CR0.

**Special Registers Altered:**

- CR0
5.9 Fixed-Point Logical, Bit, and Move Instructions

The *Logical* instructions perform bit-parallel operations on 64-bit operands. The *Bit* instructions manipulate a bit, or create a bit mask, in a register. The *Move* instructions move a register or an immediate value into a register.

The X-form Logical instructions with Rc=1, the SCI8-form Logical instructions with Rc=1, the RR-form Logical instructions with Rc=1, the *e_and2i*, and *e_and2is* instruction set the first three bits of CR field 0 as the arithmetic instructions described in Section 5.5, “Fixed-Point Arithmetic Instructions”. (Also see Section 4.1.1.) The Logical instructions do not change the SO, OV, and CA bits in the XER.

The fixed-point Logical instructions from Book I, *and*, *or*, *xor*, *nand*, *nor*, *eqv*, *andc*, *orc*, *extsb*, *extsh*, *cntlzwr*, and *popcntb* are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I; see Section 3.3.13 of Book I for the instruction definitions.

The fixed-point Logical instructions from Book I, *extsw* and *cntlzd* are available while executing in VLE mode on 64-bit implementations. The mnemonics, decoding, and semantics for these instructions are identical to those in Book I; see Section 3.3.13 of Book I for the instruction definitions.

\[
\begin{array}{cccccc}
29 & RS & RA & SH & MB & ME \\
\hline
n & SH & RA & \leftarrow & ROTL_{32}((RS)_{32:63},n) \\
\end{array}
\]

The contents of register RS are rotated \(32\) left \(SH\) bits. A mask is generated having 1-bits from bit \(MB+32\) through bit \(ME+32\) and 0-bits elsewhere. The rotated data is ANDed with the generated mask and the result is placed into register RA.

**Special Registers Altered:**

- None
### Shift Left Word Immediate (X-form)

**Instruction:**
- `e_slwi`  
- `e_slwi.`  

**Operands:**
- `RA`, `RS`, `SH`  
- `RA`, `RS`, `SH`

**Format:**
- 31  30  29  28  27  26  25  24  23  22  21  20  19  18  17  16  15  14  13  12  11  10  9  8  7  6  5  4  3  2  1  0

- `n`  
- `SH`  
- `m`  
- `RA`  

**Description:**
- The contents of the low-order 32 bits of register `RS` are shifted left `SH` bits. Bits shifted out of position 32 are lost. Zeros are supplied to the vacated positions on the right. The 32-bit result is placed into `RA 32:63`. `RA 0:31` are set to 0.

**Special Registers Altered:**
- CR0 (if `Rc=1`)

### Shift Left Word Immediate Short Form (IM5-form)

**Instruction:**
- `se_slwi`

**Operands:**
- `RX`, `UI5`

**Format:**
- 27  26  25  24  23  22  21  20  19  18  17  16  15  14  13  12  11  10  9  8  7  6  5  4  3  2  1  0

- `n`  
- `UI5`  
- `m`  
- `RX`

**Description:**
- The contents of the low-order 32 bits of register `RX` are shifted left `UI5` bits. Bits shifted out of position 32 are lost. Zeros are supplied to the vacated positions on the right. The 32-bit result is placed into `RX 32:63`. `RX 0:31` are set to 0.

**Special Registers Altered:**
- None

### Shift Left Word (RR-form)

**Instruction:**
- `se_slw`

**Operands:**
- `RX`, `RY`

**Format:**
- 16  15  14  13  12  11  10  9  8  7  6  5  4  3  2  1  0

- `n`  
- `RY`  
- `m`  
- `RX`

**Description:**
- The contents of the low-order 32 bits of register `RX` are shifted left the number of bits specified by `(RY)58:63`. Bits shifted out of position 32 are lost. Zeros are supplied to the vacated positions on the right. The 32-bit result is placed into `RX 32:63`. `RX 0:31` are set to 0. Shift amounts from 32-63 give a zero result.

**Special Registers Altered:**
- None

### Shift Right Algebraic Word Immediate (IM5-form)

**Instruction:**
- `se_srawi`

**Operands:**
- `RX`, `UI5`

**Format:**
- 26  25  24  23  22  21  20  19  18  17  16  15  14  13  12  11  10  9  8  7  6  5  4  3  2  1  0

- `n`  
- `UI5`  
- `m`  
- `RX`

**Description:**
- The contents of the low-order 32 bits of register `RX` are shifted right `UI5` bits. Bits shifted out of position 63 are lost, and bit 32 of `RX` is replicated to fill the vacated positions on the left. Bit 32 of `RX` is replicated to fill `RX 0:31` and the 32-bit result is placed into `RX 32:63`. `CA` is set to 1 if the low-order 32 bits of register `RX` contain a negative value and any 1-bits are shifted out of bit position 63; otherwise `CA` is set to 0. A shift amount of zero causes `RX` to receive `EXTS((RX)32:63)`, and `CA` to be set to 0.

**Special Registers Altered:**
- `CA`
Shift Right Algebraic Word  

**RR-form**

se_sraw RX,RY

<table>
<thead>
<tr>
<th>16</th>
<th>1</th>
<th>RY</th>
<th>RX</th>
</tr>
</thead>
</table>

\[
n \leftarrow (RY)_{59:63}
\]
\[
r \leftarrow \text{ROTL}_{32}((RX)_{32:63}, 64-n)
\]
\[
\text{if } (RY)_{58} = 0 \text{ then } m \leftarrow \text{MASK}(n+32, 63)
\]
\[
\text{else } \quad m \leftarrow 64_{0}
\]
\[
s \leftarrow (RX)_{32}
\]
\[
RX \leftarrow r \& m \mid (r \& \neg m)_{32:63} \neq 0
\]
\[
CA \leftarrow s \& ((r \& \neg m)_{32,63} \neq 0)
\]

The contents of the low-order 32 bits of register RX are shifted right the number of bits specified by \((RY)_{58:63}\). Bits shifted out of position 63 are lost, and bit 32 of RX is replicated to fill the vacated positions on the left. Bits 32 of RX is replicated to fill RX_{0:31} and the 32-bit result is placed into RX_{32:63}. CA is set to 1 if the low-order 32 bits of register RX contain a negative value and any 1-bits are shifted out of bit position 63; otherwise CA is set to 0. A shift amount of zero causes RX to receive \(\text{EXTS}((RX)_{32:63})\), and CA to be set to 0. Shift amounts from 32-63 give a result of 64 sign bits, and cause CA to receive the sign bit of \((RX)_{32:63}\).

Special Registers Altered:

- CA

Chapter 6. Storage Control Instructions

6.1 Storage Synchronization Instructions

The memory synchronization instructions implemented by category VLE are identical in semantics to those defined in Book II and Book III-E. The se_isync instruction is defined by category VLE, but has the same semantics as isync.

The Load and Reserve and Store Conditional instructions from Book II, lbarx, lharx, lwarx, stbcx, sthcx, and stwcx, are available while executing in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book II; see Section 4.4.2 of Book II for the instruction definitions.

The Load and Reserve and Store Conditional instructions from Book II, ldarx and stdcx, are available while executing in VLE mode on 64-bit implementations. The mnemonics, decoding, and semantics for those instructions are identical to those in Book II; see Section 4.4.2 of Book II for the instruction definitions.

The Memory Barrier instructions from Book II, sync and mbar are available while executing in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book II; see Section 4.4.3 of Book II for the instruction definitions.

The wait instruction from Book II is available while executing in VLE mode if the category Wait is implemented. The mnemonics, decoding, and semantics for wait are identical to those in Book II; see Section 4.4 of Book II for the instruction definition.

Instruction Synchronize C-form

se_isync

01 15

Executing an se_isync instruction ensures that all instructions preceding the se_isync instruction have completed before the se_isync instruction completes, and that no subsequent instructions are initiated until after the se_isync instruction completes. It also ensures that all instruction cache block invalidations caused by icbi instructions preceding the se_isync instruction have been performed with respect to the processor executing the se_isync instruction, and then causes any prefetched instructions to be discarded.

Except as described in the preceding sentence, the se_isync instruction may complete before storage accesses associated with instructions preceding the se_isync instruction have been performed. This instruction is context synchronizing.

The se_isync instruction has identical semantics to the Book II isync instruction, but has a different encoding.

Special Registers Altered:

None
6.2 Cache Management Instructions

Cache management instructions implemented by category VLE are identical to those defined in Book II and Book III-E.

The Cache Management instructions from Book II, \texttt{dcba}, \texttt{dcbf}, \texttt{dcbst}, \texttt{dcbt}, \texttt{dcbtst}, \texttt{dcbz}, \texttt{icbi}, and \texttt{icbt} are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book II; see Section 4.3 of Book II for the instruction definitions.

The Cache Management instruction from Book III-E, \texttt{dcbi} is available while executing in VLE mode. The mnemonics, decoding, and semantics for this instruction are identical to those in Book III-E; see Section 6.11.1 of Book III-E for the instruction definition.

6.3 Cache Locking Instructions

Cache locking instructions implemented by category VLE are identical to those defined in Book III-E. If the Cache Locking instructions are implemented in category VLE, the Category: Embedded Cache Locking must also be implemented.

The Cache Locking instructions from Book III-E, \texttt{dcbtls}, \texttt{dcbtstls}, \texttt{dcblc}, \texttt{dcblq}, \texttt{icbtls}, \texttt{icblq}, and \texttt{icblc} are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book III-E; see Section 6.11.2 of Book III-E for the instruction definitions.

6.4 TLB Management Instructions

The TLB Management instructions implemented by category VLE are identical to those defined in Book III-E.

The TLB Management instructions from Book III-E, \texttt{tlbre}, \texttt{tlbwe}, \texttt{tlbivax}, \texttt{tlbilx}, \texttt{tlbsync}, \texttt{tlbsrx}, \texttt{<E.TWC>}, and \texttt{tlbsx} are available while executing in VLE mode. The mnemonics, decoding, and semantics for these instructions are identical to those in Book III-E. See Section 6.11.4.9 of Book III-E.

Instructions and resources described in Chapter 6 of Book III-E are available if the appropriate category is implemented.

6.5 Instruction Alignment and Byte Ordering

Only Big-Endian instruction memory is supported when executing from a page of VLE instructions. Attempting to fetch VLE instructions from a page marked as Little-Endian generates an instruction storage interrupt byte-ordering exception.
Chapter 7. Additional Categories Available in VLE

Instructions and resources from categories other than Base and Embedded are available in VLE. These include categories for which all the instructions in the category use primary opcode 4 or primary opcode 31.

7.1 Move Assist

Move Assist instructions implemented by category VLE are identical to those defined in Book I. If category Move Assist is supported in non-VLE mode, Move Assist instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Section 3.3.7 of Book I for the instruction definitions.

7.2 Vector

Vector instructions implemented by category VLE are identical to those defined in Book I. If category Vector is supported in non-VLE mode, Vector instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Chapter 5 of Book I for the instruction definitions.

7.3 Signal Processing Engine

Signal Processing Engine instructions implemented by category VLE are identical to those defined in Book I. If category Signal Processing Engine is supported in non-VLE mode, Signal Processing Engine instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Chapter 8 of Book I for the instruction definitions.

7.4 Embedded Floating Point

Embedded Floating Point instructions implemented by category VLE are identical to those defined in Book I. If category SPE.Embedded Float Scalar Double, SPE.Embedded Float Scalar Single, or SPE.Embedded Float Vector is supported in non-VLE mode, the appropriate Embedded Floating Point instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Chapter 9 of Book I for the instruction definitions.

7.5 Legacy Move Assist

Legacy Move Assist instructions implemented by category VLE are identical to those defined in Book I. If category Legacy Move Assist is supported in non-VLE mode, Legacy Move Assist instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book I; see Chapter 10 of Book I for the instruction definitions.

7.6 Embedded Hypervisor

Embedded Hypervisor instructions implemented by category VLE are not identical to those defined in Book III - E. The _ehpriv instruction is identical in mnemonics, decoding, and semantics to the instruction defined in Book III-E. See Section 4.3.1 of Book III-E for the instruction definition. The sc instruction which provides a LEV field for executing calls to the hypervisor software is implemented as e_sc, which is defined in Section 4.3 of Book VLE. The rfgi instruction is implemented as se_rfgi, which is also defined in Section 4.3 of Book VLE. If Category: Embedded Hypervisor is supported in non-VLE mode, Embedded Hypervisor instructions are also supported in VLE mode.

7.7 External PID

External Process ID instructions implemented by category VLE are identical to those defined in Book III-E. If Category: Embedded External PID is supported in non-VLE mode, External Process ID instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book III-E; see Chapter 5.3.7 of Book III-E for the instruction definitions.
7.8 Embedded Performance Monitor

*Embedded Performance Monitor* instructions implemented by category VLE are identical to those defined in Book III-E. If Category: Embedded.Performance Monitor is supported in non-VLE mode, *Embedded Performance Monitor* instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book III-E; see Appendix D of Book III-E for the instruction definitions.

7.9 Processor Control

*Processor Control* instructions implemented by category VLE are identical to those defined in Book III-E. If Category: Embedded.Processor Control is supported in non-VLE mode, *Processor Control* instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book III-E; see Chapter 11 for the instruction definitions.

7.10 Decorated Storage

*Decorated Storage* instructions implemented by category VLE are identical to those defined in Book II. If category Decorated Storage is supported in non-VLE mode, Decorated Storage instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book II; see Chapter 8 of Book II for the instruction definitions.

7.11 Embedded Cache Initialization

*Embedded Cache Initialization* instructions implemented by category VLE are identical to those defined in Book III-E. If Category: Embedded.Cache Initialization is supported in non-VLE mode, *Embedded Cache Initialization* instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book III-E; Chapter A.1 of Book III-E for the instruction definitions.

7.12 Embedded Cache Debug

*Embedded Cache Debug* instructions implemented by category VLE are identical to those defined in Book III-E. If Category: Embedded.Cache Debug is supported in non-VLE mode, *Embedded Cache Debug* instructions are also supported in VLE mode. The mnemonics, decoding, and semantics for those instructions are identical to those in Book III-E; Chapter A.2 of Book III-E for the instruction definitions.
## Appendix A. VLE Instruction Set Sorted by Mnemonic

This appendix lists all the instructions available in VLE mode in the Power ISA, in order by mnemonic. Opcodes that are not defined below are treated as illegal by category VLE.

### Appendix A. VLE Instruction Set Sorted by Mnemonic

**Form** | **Opcode (hexadecimal)\(^2\)** | **Mode Dep.\(^1\)** | **Priv\(^1\)** | **Cat\(^1\)** | **Mnemonic** | **Instruction**
--- | --- | --- | --- | --- | --- | ---
VX | 1000020C | V |  |  | vsplitb | Vector Splat Byte
VX | 1000024C | V |  |  | vsplitlth | Vector Splat Halfword
VX | 1000030C | V |  |  | vsplitlsb | Vector Splat Immediate Signed Byte
VX | 1000034C | V |  |  | vsplilsh | Vector Splat Immediate Signed Halfword
VX | 1000038C | V |  |  | vsplisw | Vector Splat Immediate Signed Word
VX | 1000028C | V |  |  | vsplthw | Vector Splat Word
VX | 100002C4 | V |  |  | vsr | Vector Shift Right
VX | 10000304 | V |  |  | vsrab | Vector Shift Right Algebraic Word
VX | 10000344 | V |  |  | vsrah | Vector Shift Right Algebraic Halfword
VX | 10000384 | V |  |  | vsraw | Vector Shift Right Algebraic Word
VX | 10000204 | V |  |  | vsrb | Vector Shift Right Byte
VX | 10000244 | V |  |  | vsrh | Vector Shift Right Halfword
VX | 1000044C | V |  |  | vsro | Vector Shift Right by Octet
VX | 10000284 | V |  |  | vsrw | Vector Shift Right Word
VX | 10000580 | V |  |  | vsubcuw | Vector Subtract and Write Carry-Out Unsigned Word
VX | 100004A | V |  |  | vsubfp | Vector Subtract Single-Precision
VX | 10000700 | V |  |  | vsubsbs | Vector Subtract Signed Byte Saturate
VX | 10000740 | V |  |  | vsubshs | Vector Subtract Signed Halfword Saturate
VX | 10000400 | V |  |  | vsubsws | Vector Subtract Signed Word Saturate
VX | 10000600 | V |  |  | vsububs | Vector Subtract Unsigned Byte Saturate
VX | 10000440 | V |  |  | vsubuhm | Vector Subtract Unsigned Halfword Modulo
VX | 10000640 | V |  |  | vsuhbs | Vector Subtract Unsigned Halfword Saturate
VX | 10000480 | V |  |  | vsuwm | Vector Subtract Unsigned Word Modulo
VX | 10000680 | V |  |  | vsubws | Vector SubtractUnsigned Word Saturate
VX | 10000688 | V |  |  | vsum2sws | Vector Sum across Half Signed Word Saturate
VX | 10000708 | V |  |  | vsum4sbs | Vector Sum across Quarter Signed Byte Saturate
VX | 10000648 | V |  |  | vsum4shs | Vector Sum across Quarter Signed Halfword Saturate
VX | 10000608 | V |  |  | vsum4ubs | Vector Sum across Quarter Unsigned Byte Saturate
VX | 10000788 | V |  |  | vsumsws | Vector Sum across Signed Word Saturate
VX | 1000034E | V |  |  | vupkpx | Vector Unpack High Pixel
VX | 1000020E | V |  |  | vupkshs | Vector Unpack High Signed Byte
VX | 1000024E | V |  |  | vupksh | Vector Unpack High Signed Halfword
VX | 100003CE | V |  |  | vupklpx | Vector Unpack Low Pixel
VX | 1000028E | V |  |  | vupklsb | Vector Unpack Low Signed Byte
VX | 100002CE | V |  |  | vupks | Vector Unpack Low Signed Halfword
VX | 100004C4 | V |  |  | vxor | Vector Logical XOR
X | 7C000007C | P |  |  | wt | wait
X | 7C0000106 | P |  |  | wrtee | Write MSR External Enable
X | 7C0000146 | P |  |  | wrteei | Write MSR External Enable Immediate
X | 7C0000278 | SR | B |  | xor[.] | XOR

---

1. See the key to the mode dependency and privilege columns on page 1484 and the key to the category column in Section 1.3.5 of Book I.

2. For 16-bit instructions, the “Opcode” column represents the 16-bit hexadecimal instruction encoding with the opcode and extended opcode in the corresponding fields in the instruction, and with 0’s in bit positions which are not opcode bits; dashes are used following the opcode to indicate the form is a 16-bit instruction. For 32-bit instructions, the “Opcode” column represents the 32-bit hexadecimal instruction encoding with the opcode, extended opcode, and other fields with fixed values in the corresponding fields in the instruction, and with 0...s in bit positions which are not opcode, extended opcode or fixed value bits.
Appendix B. VLE Instruction Set Sorted by Opcode

This appendix lists all the instructions available in VLE mode in the Power ISA, in order by opcode. Opcodes that are not defined below are treated as illegal by category VLE.

¹ See the key to the mode dependency and privilege column below and the key to the category column in Section 1.3.5 of Book I.

²For 16-bit instructions, the “Opcode” column represents the 16-bit hexadecimal instruction encoding with the opcode and extended opcode in the corresponding fields in the instruction, and with 0’s in bit positions which are not opcode bits; dashes are used following the opcode to indicate the form is a 16-bit instruction. For 32-bit instructions, the “Opcode” column represents the 32-bit hexadecimal instruction encoding with the opcode, extended opcode, and other fields with fixed values in the corresponding fields in the instruction, and with 0’s in bit positions which are not opcode, extended opcode or fixed value bits.

Mode Dependency and Privilege Abbreviations

Except as described below and in Section 1.10.3, “Effective Address Calculation”, in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

Mode Dep. Description

CT If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.

SR The setting of status registers (such as XER and CR0) is mode-dependent.
Mode Dep. Description

32 The instruction must be executed only in 32-bit mode.

64 The instruction must be executed only in 64-bit mode.

Key to Privilege Column

Priv. Description

P Denotes a privileged instruction.

O Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor, for mtspri), depending on the SPR or PMR number.

M Denotes an instruction that is treated as privileged or nonprivileged, depending on the value of the UCLE bit of the MSR.

H Denotes an instruction that can be executed only in hypervisor state.
Appendices:

Power ISA Book I-III Appendices
Appendix A. Incompatibilities with the POWER Architecture

This appendix identifies the known incompatibilities that must be managed in the migration from the POWER Architecture to the Power ISA. Some of the incompatibilities can, at least in principle, be detected by the processor, which could trap and let software simulate the POWER operation. Others cannot be detected by the processor even in principle.

In general, the incompatibilities identified here are those that affect a POWER application program. Incompatibilities for instructions that can be used only by POWER operating system programs are not necessarily discussed. Discussion of incompatibilities that pertain only to operating system programs assumes the Server environment (because there is no need for POWER operating system programs to run in the Embedded environment).

A.1 New Instructions, Formerly Privileged Instructions

Instructions new to Power ISA typically use opcode values (including extended opcode) that are illegal in POWER. A few instructions that are privileged in POWER (e.g., 
\[ \text{dclz} \] called \[ \text{dcbz} \] in Power ISA) have been made nonprivileged in Power ISA. Any POWER program that executes one of these now-valid or now-nonprivileged instructions, expecting to cause the system illegal instruction error handler or the system privileged instruction error handler to be invoked, will not execute correctly on Power ISA.

A.2 Newly Privileged Instructions

The following instructions are nonprivileged in POWER but privileged in Power ISA.
- `mfmsr`
- `mfsr`

A.3 Reserved Fields in Instructions

These fields are shown with "/"s in the instruction layouts. In both POWER and Power ISA these fields are ignored by the processor. The Power ISA states that these fields must contain zero. The POWER Architecture lacks such a statement, but it is expected that essentially all POWER programs contain zero in these fields.

In several cases the Power ISA assumes that reserved fields in POWER instructions indeed contain zero. The cases include the following.
- `bclr[l]` and `bcctr[l]` assume that bits 19:20 in the POWER instructions contain zero.
- `cmpi`, `cmp`, `cmpli`, and `cmpl` assume that bit 10 in the POWER instructions contains zero.
- `mtspr` and `mfspr` assume that bits 16:20 in the POWER instructions contain zero.
- `mtcrf` and `mfcr` assume that bit 11 in the POWER instructions contains zero.
- Synchronize assumes that bits 9:10 in the POWER instruction (\[ \text{dcs} \]) contain zero. (This assumption provides compatibility for application programs, but not necessarily for operating system programs; see Section A.22.)
- `mtmsr` assumes that bit 15 in the POWER instruction contains zero.

A.4 Reserved Bits in Registers

Both POWER and Power ISA permit software to write any value to these bits. However in POWER reading such a bit always returns 0, while in Power ISA reading it may return either 0 or the value that was last written to it.

A.5 Alignment Check

The POWER MSR \[ \text{AL} \] bit (bit 24) is no longer supported; the corresponding Power ISA MSR bit, bit 56, is reserved. The low-order bits of the EA are always used. (Notice that the value 0 — the normal value for a reserved bit — means "ignore the low-order EA bits" in
POWER, and the value 1 means "use the low-order EA bits"). POWER-compatible operating system code will probably write the value 1 to this bit.

A.6 Condition Register

The following instructions specify a field in the CR explicitly (via the BF field) and also, in POWER, use bit 31 as the Record bit. In Power ISA, bit 31 is a reserved field for these instructions and is ignored by the processor. In POWER, if bit 31 contains 1 the instructions execute normally (i.e., as if the bit contained 0) except as follows:

- `cmp` CR0 is undefined if Rc=1 and BF≠0
- `cmpl` CR0 is undefined if Rc=1 and BF≠0
- `mcrxr` CR0 is undefined if Rc=1 and BF≠0
- `fcmpu` CR1 is undefined if Rc=1
- `fcmpo` CR1 is undefined if Rc=1
- `mcrfs` CR1 is undefined if Rc=1 and BF≠1

A.7 LK and Rc Bits

For the instructions listed below, if bit 31 (LK or Rc bit in POWER) contains 1, in POWER the instruction executes as if the bit contained 0 except as follows: if LK=1, the Link Register is set (to an undefined value, except for `svc`); if Rc=1, Condition Register Field 0 or 1 is set to an undefined value. In Power ISA, bit 31 is a reserved field for these instructions and is ignored by the processor.

Power ISA instructions for which bit 31 is the LK bit in POWER:

- `sc` (svc in POWER)
- the Condition Register Logical instructions
- `mcrf`
- `isync` (ics in POWER)

Power ISA instructions for which bit 31 is the Rc bit in POWER:

- fixed-point X-form Load and Store instructions
- fixed-point X-form Compare instructions
- the X-form Trap instruction
- `mtspr`, `mfspr`, `mtcrf`, `mcrf`, `mtocrf`, `mtocrf`
- floating-point X-form Load and Store instructions
- floating-point Compare instructions
- `mcrfs`
- `dcbz` (dclz in POWER)

A.8 BO Field

POWER shows certain bits in the BO field — used by Branch Conditional instructions — as "x". Although the POWER Architecture does not say how these bits are to be interpreted, they are in fact ignored by the processor.

Power ISA shows these bits as "z", "a", or "t". The "z" bits are ignored, as in POWER. However, the "a" and "t" bits can be used by software to provide a hint about how the branch is likely to behave. If a POWER program has the "wrong" value for these bits, the program will produce the same results as on POWER but performance may be affected.

A.9 BH Field

Bits 19:20 of the Branch Conditional to Link Register and Branch Conditional to Count Register instructions are reserved in POWER but are defined as a branch hint (BH) field in Power ISA. Because these bits are hints, they may affect performance but do not affect the results of executing the instruction.

A.10 Branch Conditional to Count Register

For the case in which the Count Register is decremented and tested (i.e., the case in which BO₂=0), POWER specifies only that the branch target address is undefined, with the implication that the Count Register, and the Link Register if LK=1, are updated in the normal way. Power ISA specifies that this instruction form is invalid.

A.11 System Call

There are several respects in which Power ISA is incompatible with POWER for System Call instructions — which in POWER are called Supervisor Call instructions.

- POWER provides a version of the Supervisor Call instruction (bit 30 = 0) that allows instruction fetching to continue at any one of 128 locations. It is used for "fast SVCs". Power ISA provides no such version: if bit 30 of the instruction is 0 the instruction form is invalid.
- POWER provides a version of the Supervisor Call instruction (bits 30:31 = 0b11) that resumes instruction fetching at one location and sets the Link Register to the address of the next instruction. Power ISA provides no such version: bit 31 is a reserved field.
- For POWER, information from the MSR is saved in the Count Register. For Power ISA this information is saved in SRR1.
- In POWER bits 16:19 and 27:29 of the instruction comprise defined instruction fields or a portion thereof, while in Power ISA these bits comprise reserved fields.
In POWER bits 20:26 of the instruction comprise a portion of the SV field, while in Power ISA these bits comprise the LEV field.

POWER saves the low-order 16 bits of the instruction, in the Count Register. Power ISA does not save them.

The settings of MSR bits by the associated interrupt differ between POWER and Power ISA; see POWER Processor Architecture and Book III.

A.12 Fixed-Point Exception Register (XER)

Bits 48:55 of the XER are reserved in Power ISA, while in POWER the corresponding bits (16:23) are defined and contain the comparison byte for the \texttt{lscbx} instruction (which Power ISA lacks).

A.13 Update Forms of Storage Access Instructions

Power ISA requires that RA not be equal to either RT (fixed-point Load only) or 0. If the restriction is violated the instruction form is invalid. POWER permits these cases, and simply avoids saving the EA.

A.14 Multiple Register Loads

Power ISA requires that RA, and RB if present in the instruction format, not be in the range of registers to be loaded, while POWER permits this and does not alter RA or RB in this case. (The Power ISA restriction applies even if RA=0, although there is no obvious benefit to the restriction in this case since RA is not used to compute the effective address if RA=0.) If the Power ISA restriction is violated, either the system illegal instruction error handler is invoked or the results are boundedly undefined. The instructions affected are:

- \texttt{lmw} (\texttt{lm} in POWER)
- \texttt{lswi} (\texttt{lsi} in POWER)
- \texttt{lswx} (\texttt{lsx} in POWER)

For example, an \texttt{lmw} instruction that loads all 32 registers is valid in POWER but is an invalid form in Power ISA.

A.15 Load/Store Multiple Instructions

There are two respects in which Power ISA is incompatible with POWER for Load Multiple and Store Multiple instructions.

If the EA is not word-aligned, in Power ISA either an Alignment exception occurs or the addressed bytes are loaded, while in POWER an Alignment interrupt occurs if \texttt{MSRAL=1} (the low-order two bits of the EA are ignored if \texttt{MSRAL=0}).

In Power ISA the instruction may be interrupted by a system-caused interrupt, while in POWER the instruction cannot be thus interrupted.

A.16 Move Assist Instructions

There are several respects in which Power ISA is incompatible with POWER for Move Assist instructions.

- In Power ISA an \texttt{lswx} instruction with zero length leaves the contents of RT undefined (if RT≠RA and RT≠RB) or is an invalid instruction form (if RT=RA or RT=RB), while in POWER the corresponding instruction (\texttt{lsx}) is a no-op in these cases.

In Power ISA a Move Assist instruction may be interrupted by a system-caused interrupt, while in POWER the instruction cannot be thus interrupted.

A.17 Move To/From SPR

There are several respects in which Power ISA is incompatible with POWER for Move To/From Special Purpose Register instructions.

- The SPR field is ten bits long in Power ISA, but only five in POWER (see also Section A.3, “Reserved Fields in Instructions”).
- \texttt{mfspr} can be used to read the Decrementer in problem state in POWER, but only in privileged state in Power ISA.

If the SPR value specified in the instruction is not one of the defined values, POWER behaves as follows.
- If the instruction is executed in problem state and \texttt{SPR0=1}, a Privileged Instruction type Program interrupt occurs. No architected registers are altered except those set by the interrupt.
- Otherwise no architected registers are altered.

In this same case, Power ISA behaves as follows.
- If the instruction is executed in problem state, a Hypervisor Emulation Assistance interrupt occurs if \texttt{spr0=0} and a Privileged Instruction type Program interrupt occurs if \texttt{spr0=1}. No architected registers are altered except those set by the interrupt.
- If the instruction is executed in privileged state, a Hypervisor Emulation Assistance interrupt occurs if the SPR value is 0 or, for \texttt{mfspr} only, if the SPR value is 4, 5, or 6. In
these cases no architected registers are altered except those set by the interrupt. Otherwise no operation is performed. (See Section 4.4.4, “Move To/From System Register Instructions” in Book III-S.)

A.18 Effects of Exceptions on FPSCR Bits FR and FI

For the following cases, POWER does not specify how FR and FI are set, while Power ISA preserves them for Invalid Operation Exception caused by a Compare instruction, sets FI to 1 and FR to an undefined value for disabled Overflow Exception, and clears them otherwise.

- Invalid Operation Exception (enabled or disabled)
- Zero Divide Exception (enabled or disabled)
- Disabled Overflow Exception

A.19 Store Floating-Point Single Instructions

There are several respects in which Power ISA is incompatible with POWER for Store Floating-Point Single instructions.

- POWER uses FPSCR\textsubscript{UE} to help determine whether denormalization should be done, while Power ISA does not. Using FPSCR\textsubscript{UE} is in fact incorrect: if FPSCR\textsubscript{UE}=1 and a denormalized single-precision number is copied from one storage location to another by means of \textit{lfs} followed by \textit{stfs}, the two “copies” may not be the same.

- For an operand having an exponent that is less than 874 (unbiased exponent less than \textasciitilde -149), POWER stores a zero (if FPSCR\textsubscript{UE}=0) while Power ISA stores an undefined value.

A.20 Move From FPSCR

POWER defines the high-order 32 bits of the result of \textit{mfs} to be 0xFFFF_FFFF, while Power ISA copies the high-order 32-bits of the FPSCR.

A.21 Zeroing Bytes in the Data Cache

The \textit{dclz} instruction of POWER and the \textit{dcbz} instruction of Power ISA have the same opcode. However, the functions differ in the following respects.

- \textit{dclz} clears a line while \textit{dcbz} clears a block.
- \textit{dclz} saves the EA in RA (if RA\neq 0) while \textit{dcbz} does not.
- \textit{dclz} is privileged while \textit{dcbz} is not.

A.22 Synchronization

The \textit{Synchronize} instruction (called \textit{dcs} in POWER) and the \textit{isync} instruction (called \textit{ics} in POWER) cause more pervasive synchronization in Power ISA than in POWER. However, unlike \textit{dcs}, \textit{Synchronize} does not wait until data cache block writes caused by preceding instructions have been performed in main storage. Also, \textit{Synchronize} has an L field while \textit{dcs} does not, and some uses of the instruction by the operating system require L=2<S>. (The L field corresponds to reserved bits in \textit{dcs} and hence is expected to be zero in POWER programs; see Section A.3.)

A.23 Move To Machine State Register Instruction

The \textit{mtmsr} instruction has an L field in Power ISA but not in POWER. The function of the variant of \textit{mtmsr} with L=1 differs from the function of the instruction in the POWER architecture in the following ways.

- In Power ISA, this variant of \textit{mtmsr} modifies only the EE and RI bits of the MSR, while in the POWER \textit{mtmsr} modifies all bits of the MSR.

- This variant of \textit{mtmsr} is execution synchronizing in Power ISA but is context synchronizing in POWER. (The POWER architecture lacks Power ISA’s distinction between execution synchronization and context synchronization. The statement in the POWER architecture specification that \textit{mtmsr} is “synchronizing” is equivalent to stating that the instruction is context synchronizing.)

Also, \textit{mtmsr} is optional in Power ISA but required in POWER.

A.24 Direct-Store Segments

POWER’s direct-store segments are not supported in Power ISA.

A.25 Segment Register Manipulation Instructions

The definitions of the four Segment Register Manipulation instructions \textit{mtsr}, \textit{mtsri}, \textit{mfsr}, and \textit{mfsri} differ in two respects between POWER and Power ISA. Instructions similar to \textit{mtsri} and \textit{mfsri} are called \textit{mtsri} and \textit{mfsri} in POWER.

- \textit{mfsr} and \textit{mfsri} are problem state instructions in POWER, while \textit{mfsr} and \textit{mfsri} are privileged in Power ISA.

- function: the “indirect” instructions (\textit{mtsri} and \textit{mfsri}) in POWER use an RA register in computing the Segment Register number, and the computed EA is stored into RA (if
Appendix A. Incompatibilities with the POWER Architecture

A.26 TLB Entry Invalidation

The `tlbi` instruction of POWER and the `tlbie` instruction of Power ISA have the same opcode. However, the functions differ in the following respects.

- `tlbi` computes the EA as \((RA) \land 0 + (RB)\), while `tlbie` lacks an RA field and computes the EA and related information as \((RB)\).
- `tlbi` saves the EA in RA (if RA\(\neq 0\)), while `tlbie` lacks an RA field and does not save the EA.
- For `tlbi` the high-order 36 bits of RB are used in computing the EA, while for `tlbie` these bits contain additional information that is not directly related to the EA.
- For `tlbi` has no RS operand, while for `tlbie` the \(RS\) is an LPID value used to qualify the TLB invalidation.

Also, `tlbi` is required in POWER whereas `tlbie` is optional in Power ISA.

A.27 Alignment Interrupts

Placing information about the interrupting instruction into the DSISR and the DAR when an Alignment interrupt occurs is optional in Power ISA but required in POWER.

A.28 Floating-Point Interrupts

POWER uses MSR bit 20 to control the generation of interrupts for floating-point enabled exceptions, and Power ISA uses the corresponding MSR bit, bit 52, for the same purpose. However, in Power ISA this bit is part of a two-bit value that controls the occurrence, precision, and recoverability of the interrupt, while in POWER this bit is used independently to control the occurrence of the interrupt (in POWER all floating-point interrupts are precise).

A.29 Timing Facilities

A.29.1 Real-Time Clock

The POWER Real-Time Clock is not supported in Power ISA. Instead, Power ISA provides a Time Base. Both the RTC and the TB are 64-bit Special Purpose Registers, but they differ in the following respects.

- The RTC counts seconds and nanoseconds, while the TB counts “ticks”. The ticking rate of the TB is implementation-dependent.
- The RTC increments discontinuously: 1 is added to RTCU when the value in RTCL passes 999,999,999. The TB increments continuously: 1 is added to TBU when the value in TBL passes 0xFFFF_FFFF.
- The RTC is written and read by the `mtspr` and `mfspr` instructions, using SPR numbers that denote the RTCU and RTCL. The TB is written and read by the same instructions using different SPR numbers.
- The SPR numbers that denote POWER's RTCL and RTCU are invalid in Power ISA.
- The RTC is guaranteed to increment at least once in the time required to execute ten \textit{Add Immediate} instructions. No analogous guarantee is made for the TB.
- Not all bits of RTCL need be implemented, while all bits of the TB must be implemented.

A.29.2 Decrementer

The Power ISA Decrementer differs from the POWER Decrementer in the following respects.

- The Power ISA DEC decrements at the same rate that the TB increments, while the POWER DEC decrements every nanosecond (which is the same rate that the RTC increments).
- Not all bits of the POWER DEC need be implemented, while all bits of the Power ISA DEC must be implemented.
- The interrupt caused by the DEC has its own interrupt vector location in Power ISA, but is considered an External interrupt in POWER.
A.30 Deleted Instructions

The following instructions are part of the POWER Architecture but have been dropped from the Power ISA.

</tbody>
</table>

(*) This instruction is privileged.

Note: Many of these instructions use the MQ register. The MQ is not defined in the Power ISA.

A.31 Discontinued Opcodes

The opcodes listed below are defined in the POWER Architecture but have been dropped from the Power ISA. The list contains the POWER mnemonic (MNEM), the primary opcode (PRI), and the extended opcode (XOP) if appropriate. The corresponding instructions are reserved in Power ISA.

Assembler Note

It might be helpful to current software writers for the Assembler to flag the discontinued POWER instructions.
A.32 POWER2 Compatibility

The POWER2 instruction set is a superset of the POWER instruction set. Some of the instructions added for POWER2 are included in the Power ISA. Those that have been renamed in the Power ISA are listed in this section, as are the new POWER2 instructions that are not included in the Power ISA. Other incompatibilities are also listed.

A.32.1 Cross-Reference for Changed POWER2 Mnemonics

The following table lists the new POWER2 instruction mnemonics that have changed in the Power ISA User Instruction Set Architecture, sorted by POWER2 mnemonic.

To determine the Power ISA mnemonic for one of these POWER2 mnemonics, find the POWER2 mnemonic in the second column of the table: the remainder of the line gives the Power ISA mnemonic and the page on which the instruction is described, as well as the instruction names.

POWER2 mnemonics that have not changed are not listed.

<table>
<thead>
<tr>
<th>Page</th>
<th>POWER2 Mnemonic</th>
<th>POWER2 Instruction</th>
<th>Power ISA Mnemonic</th>
<th>Power ISA Instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>153</td>

<td>fctiw[.]</td>
<td>Floating Convert To Integer Word</td>
</tr>
<tr>
<td>154</td>
<td>fcirz[.]</td>
<td>Floating Convert Double to Integer with Round to Zero</td>
<td>fctiwz[.]</td>
<td>Floating Convert To Integer Word with round toward Zero</td>
</tr>
</tbody>
</table>

A.32.2 Load/Store Floating-Point Double

Several of the opcodes for the Load/Store Floating-Point Quad instructions of the POWER2 architecture have been reclaimed by the Load/Store Floating-Point Double [Indexed] instructions (entries with a ‘-’ in the Power ISA column have not been reclaimed):

<table>
<thead>
<tr>
<th>Mnemonic</th>
<th>POWER2</th>
<th>POWER ISA</th>
<th>PRI</th>
<th>XOP</th>
</tr>
</thead>
<tbody>
<tr>
<td>lfpq</td>
<td>lq</td>
<td>56</td>
<td>-</td>
<td></td>
</tr>
<tr>
<td>lfpqu</td>
<td>lfdp</td>
<td>57</td>
<td>0</td>
<td></td>
</tr>
<tr>
<td>lfpqx</td>
<td>-</td>
<td>31</td>
<td>823</td>
<td></td>
</tr>
<tr>
<td>stfq</td>
<td>-</td>
<td>60</td>
<td>-</td>
<td></td>
</tr>
<tr>
<td>stfqu</td>
<td>stfdp</td>
<td>61</td>
<td>-</td>
<td></td>
</tr>
<tr>
<td>stfqux</td>
<td>-</td>
<td>31</td>
<td>951</td>
<td></td>
</tr>
<tr>
<td>stfqx</td>
<td>stfdpx</td>
<td>31</td>
<td>919</td>
<td></td>
</tr>
</tbody>
</table>

Differences between the lfstfdp[x] instructions and the POWER2 lfstfq[u][x] instructions include the following:

- The storage operand for the lfstfdp[x] instructions must be quadword aligned for optimal performance.
- The register pairs for the lfstfdp[x] instructions must be even-odd pairs, instead of any consecutive pair.
- The lfstfdp[x] instructions do not have update forms.

A.32.3 Floating-Point Conversion to Integer

The fcir and fcirz instructions of POWER2 have the same opcodes as do the fctiw and fctiwz instructions, respectively, of Power ISA. However, the functions differ in the following respects.

- fcir and fcirz set the high-order 32 bits of the target FPR to 0xFFFF_FFFF, while fctiw and fctiwz set them to an undefined value.
- Except for enabled Invalid Operation Exceptions, fcir and fcirz set the FPREF field of the FPSCR based on the result, while fctiw and fctiwz set it to an undefined value.
- fcir and fcirz do not affect the VXSNAN bit of the FPSCR, while fctiw and fctiwz do.
- fcir and fcirz set FPSCR.X to 1 for certain cases of “Large Operands” (i.e., operands that are too large to be represented as a 32-bit signed fixed-point integer), while fctiw and fctiwz do not alter it for any case of “Large Operands”. (The IEEE standard requires not altering it for “Large Operands”.)
A.32.4 Floating-Point Interrupts

POWER2 uses MSR bits 20 and 23 to control the generation of interrupts for floating-point enabled exceptions, and Power ISA uses the corresponding MSR bits, bits 52 and 55, for the same purpose. However, in Power ISA these bits comprise a two-bit value that controls the occurrence, precision, and recoverability of the interrupt, while in POWER2 these bits are used independently to control the occurrence (bit 20) and the precision (bit 23) of the interrupt. Moreover, in Power ISA all floating-point interrupts are considered Program interrupts, while in POWER2 imprecise floating-point interrupts have their own interrupt vector location.

A.32.5 Trace

The Trace interrupt vector location differs between the two architectures, and there are many other differences.

A.33 Deleted Instructions

The following instructions are new in POWER2 implementations of the POWER Architecture but have been dropped from the Power ISA.

<table>
<thead>
<tr>
<th>MNEM</th>
<th>Pri</th>
<th>XOP</th>
</tr>
</thead>
<tbody>
<tr>
<td>lfq</td>
<td>56</td>
<td>-</td>
</tr>

<td></td>
<td></td>
</tr>
<tr>
<td>stfqu</td>
<td></td>
<td></td>
</tr>
<tr>
<td>stfqx</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

A.33.1 Discontinued Opcodes

The opcodes listed below are new in POWER2 implementations of the POWER Architecture but have been dropped from the Power ISA. The list contains the POWER2 mnemonic (MNEM), the primary opcode (PRI), and the extended opcode (XOP) if appropriate. The instructions are either illegal or reserved in Power ISA; see Appendix D.
Appendix B. Platform Support Requirements

As described in Chapter 1 of Book I, the architecture is structured as a collection of categories. Each category is comprised of facilities and/or instructions that together provide a unit of functionality. The Server and Embedded categories are referred to as "special" because all implementations must support at least one of these categories. Each special category, when taken together with the Base category, is referred to as an "environment", and provides the minimum functionality required to develop operating systems and applications.

Every processor implementation supports at least one of the environments, and may also support a set of categories chosen based on the target market for the implementation. However, a Server implementation supports only those categories designated as part of the Server platform in Figure 1. To facilitate the development of operating systems and applications for a well-defined purpose or customer set, usually embodied in a unique hardware platform, this appendix documents the association between a platform and the set of categories it requires.

Adding a new platform may permit cost-performance optimization by clearly identifying a unique set of categories. However, this has the potential to fragment the application base. As a result, new platforms will be added only when the optimization benefit clearly outweighs the loss due to fragmentation.

The platform support requirements are documented in Figure 1. An “x” in a column indicates that the category is required. A “+” in a column indicates that the requirement is being phased in.

<td>x</td>
<td></td>
</tr>
</tbody>
</table>

1. If the Vector category is supported, Vector.Little-Endian is required on the Server platform.
2. Optional for the Server Platform.

Figure 2. SPR Numbers (Sheet 4 of 5)
This register is not defined for this instruction.
1 Note that the order of the two 5-bit halves of the SPR number is reversed.
2 See Section 1.3.5 of Book I. If multiple categories are listed separated by a semicolon, all the listed categories must be implemented in order for the other columns of the line to apply. A comma separates two alternatives, and takes precedence over a semicolon; e.g., the EPCR (E.HV,E;64) must be implemented if either (a) category E.HV is implemented or (b) the processor is an Embedded processor that implements the 64-Bit category.
3 This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2 of Book III-S or Chapter 2 of Book III-E as appropriate).
4 <S>This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2 of Book III-S).
5 This register cannot be directly written. Instead, bits in the register corresponding to 1 bits in (RS) can be cleared using `mtspr SPR,RS`.
6 The register can be written by the `dcread` instruction.
7 The register can be written by the `icread` instruction.
8 This register cannot be directly written. Instead, bits in the register corresponding to 0 bits in (RS) can be cleared using `mtspr SPR,RS`.
9 The value specified in register RS may be masked by the contents of the [U]AMOR before being placed into the AMR; see the `mtspr` instruction description in Book III-S.
10 The value specified in register RS may be ANDed with the contents of the AMOR before being placed into the UAMOR; see the `mtspr` instruction description in Book III-S.
11 The register is Category: Phased-in.
12 If the Embedded.Hypervisor category is supported, this register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2 of Book III-E). Otherwise the register is privileged for Embedded.
13 If the Embedded.Hypervisor category is supported, this register is a hypervisor resource and can be accessed by this instruction only in hypervisor state, and guest references to the register are redirected to the corresponding guest register (see Chapter 2 of Book III-E). Otherwise the register is privileged.
14 MMCR0_PMCC controls the availability of this SPR, and its contents depend on the privilege state in which it is accessed. See Section 9.4 for details.
15 Accesses to these SPRs are noops; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I.

SPR numbers 777-778, 783, 793-794, and 799 are reserved for the Performance Monitor. All other SPR numbers that are not shown above and are not implementation-specific are reserved.

Figure 2. SPR Numbers (Sheet 5 of 5)
Appendix D. Illegal Instructions

With the exception of the instruction consisting entirely of binary 0s, the instructions in this class are available for future extensions of the Power ISA; that is, some future version of the Power ISA may define any of these instructions to perform new functions.

The following primary opcodes are illegal.

1, 5, 6

The following primary opcodes have unused extended opcodes. Their unused extended opcodes can be determined from the opcode maps in Appendix F of Book Appendices. All unused extended opcodes are illegal.

4, 19, 30, 31, 56, 5, 58, 59, 60, 62, 63

An instruction consisting entirely of binary 0s is illegal, and is guaranteed to be illegal in all future versions of this architecture.
Appendix E. Reserved Instructions

The instructions in this class are allocated to specific purposes that are outside the scope of the Power ISA.

The following types of instruction are included in this class.

1. The instruction having primary opcode 0, except the instruction consisting entirely of binary 0s (which is an illegal instruction; see Section 1.7.2, “Illegal Instruction Class” on page 21) and the extended opcode shown below.

   256   Service Processor “Attention”

2. Instructions for the POWER Architecture that have not been included in the Power ISA. These are listed in Section A.31, “Discontinued Opcodes” and Section A.33.1, “Discontinued Opcodes”.

3. Implementation-specific instructions used to conform to the Power ISA specification.

4. Any other implementation-dependent instructions that are not defined in the Power ISA.
Appendix F. Opcode Maps

This appendix contains tables showing the opcodes and extended opcodes.

For the primary opcode table (Table 1 on page 1372), each cell is in the following format.

<table>
<thead>
<tr>
<th>Opcode in</th>
</tr>
</thead>
<tbody>
<tr>
<td>Decimal</td>
</tr>
<tr>
<td>Hexadecimal</td>
</tr>
</tbody>
</table>

  Instruction
  Mnemonic

The category abbreviations are shown on Section 1.3.5 of Book I. However, the categories "Phased-In", "Phased-Out", and floating-point "Record" are not listed in the opcode tables.

The extended opcode tables show the extended opcode in decimal, the instruction mnemonic, the category, and the instruction format. These tables appear in order of primary opcode within three groups. The first group consists of the primary opcodes that have small extended opcode fields (2-4 bits), namely 30, 58, and 62. The second group consists of primary opcodes that have 11-bit extended opcode fields. The third group consists of primary opcodes that have 10-bit extended opcode fields. The tables for the second and third groups are rotated.

In the extended opcode tables several special markings are used.

- A prime (') following an instruction mnemonic denotes an additional cell, after the lowest-numbered one, used by the instruction. For example, `subfc` occupies cells 8 and 520 of primary opcode 31, with the former corresponding to OE=0 and the latter to OE=1. Similarly, `sradi` occupies cells 826 and 827, with the former corresponding to sh5=0 and the latter to sh5=1 (the 9-bit extended opcode 413, shown on page 100, excludes the sh5 bit).

- Two vertical bars (||) are used instead of primed mnemonics when an instruction occupies an entire column of a table. The instruction mnemonic is repeated in the last cell of the column.

- For primary opcode 31, an asterisk (*) in a cell that would otherwise be empty means that the cell is reserved because it is "overlaid", by a fixed-point or `Storage Access` instruction having only a primary opcode, by an instruction having an extended opcode in primary opcode 30, 58, or 62, or by a potential instruction in any of the categories just mentioned. The overlaying instruction, if any, is also shown. A cell thus reserved should not be assigned to an instruction having primary opcode 31. (The overlaying is a consequence of opcode decoding for fixed-point instructions: the primary opcode, and the extended opcode if any, are mapped internally to a 10-bit "compressed opcode" for ease of subsequent decoding on some implementations that complied with previous versions of the architecture.)

- Parentheses around the opcode or extended opcode mean that the instruction was defined in earlier versions of the Power ISA but is no longer defined in the Power ISA.

- Curly brackets around the opcode or extended opcode mean that the instruction will be defined in future versions of the Power ISA.

- `long` is used as filler for mnemonics that are longer than a table cell.

An empty cell, a cell containing only an asterisk, or a cell in which the opcode or extended opcode is parenthesized, corresponds to an illegal instruction.

The instruction consisting entirely of binary 0s causes the system illegal instruction error handler to be invoked for all members of the POWER family, and this is likely to remain true in future models (it is guaranteed in the Power ISA). An instruction having primary opcode 0 but not consisting entirely of binary 0s is reserved except for the following extended opcode (instruction bits 21:30).

1 See the key to the mode dependency and privilege columns on page 1484 and the key to the category column in Section 1.3.5 of Book I.
Mode Dependency and Privilege Abbreviations

Except as described below and in Section 1.10.3, “Effective Address Calculation”, in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

Key to Mode Dependency Column

<table>
<thead>
<tr>
<th>Mode Dep.</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CT</td>
<td>If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.</td>
</tr>
<tr>
<td>SR</td>
<td>The setting of status registers (such as XER and CR0) is mode-dependent.</td>
</tr>
<tr>
<td>32</td>
<td>The instruction can be executed only in 32-bit mode.</td>
</tr>
<tr>
<td>64</td>
<td>The instruction can be executed only in 64-bit mode.</td>
</tr>
</tbody>
</table>

Key to Privilege Column

<table>
<thead>
<tr>
<th>Priv.</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>P</td>
<td>Denotes a privileged instruction.</td>
</tr>
<tr>
<td>O</td>
<td>Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor, for mtspri), depending on the SPR or PMR number.</td>
</tr>
<tr>
<td>H</td>
<td>Denotes an instruction that can be executed only in hypervisor state &lt;S,E,HV&gt;</td>
</tr>
<tr>
<td>PH</td>
<td>Denotes a hypervisor privileged instruction if Category Embedded.Hypervisor is implemented; otherwise denotes a privileged instruction.</td>
</tr>
<tr>
<td>M</td>
<td>Denotes an instruction that is treated as privileged or nonprivileged, depending on the value of the UCLE bit in the MSR.</td>
</tr>
</tbody>
</table>
